PRINTED IN THE UNITED STATES OF AMERICA

FOREWORD

This, the 185th volume of the Transactions of the American Institute of Mining and Metallurgical Engineers, contains publications, in new format, of the Metals Branch, and represents another milestone in the science and technology of metals. For the first time the technical papers of the three metals divisions (Institute of Metals, Iron and Steel, and Extractive Metallurgy) are presented in a unit.

The majority of members will appreciate the fact that the vast number of technical papers necessitates the most economical form of publication. Moreover, by this method members obtain at approximately the cost of one volume what was previously published in three. In this period of rapid technologic developments, having available the papers in related fields is of inestimable value.

The discussions are grouped in two sections of the volume. The location of the discussion of a particular paper is listed immediately following the title of that paper in the table of contents. It was not possible to publish the discussions of the papers presented at the 1948 IMD Fall Meeting in Volume 180 (1949 I.M.D. Volume) due to the mechanics inherent in the change of page size. These discussions may be found on pages 297 to 346 of this volume. The discussion of 1949 Annual Meeting papers of all three divisions are on pages 826 to 897. Discussion of papers presented at the 1949 Fall Meetings and 1950 Annual Meeting will appear in the 1950 Transactions Volume 188.

The breadth of scope of the papers from the three metals divisions, which ranges from the highly theoretical to the very practical, is unsurpassed by any other publication in the metallurgical field. It is gratifying to note the high quality of research and development being carried out in the laboratories and plants of the country. The knowledge made available and the stimulation provided by publication are definite assurances of continued progress.

I would like to express my sincerest thanks to the officers of the divisions, members of the publication and program committees, and the headquarters staff, who have worked so unstintingly to produce this outstanding metallurgical volume. Special words of appreciation should be given to the newly formed Extractive Metallurgy Division which in a single year has become a lusty member of the Metals Branch.

FEBRUARY 9, 1950
BARBER, N. J.

A. A. SMITH, JR., *Chairman*
Metals Branch A.I.M.E.

TECHNICAL PAPERS

Institute of Metals Division

| | PAGE |
|---|------|
| Plastic Deformation Waves in Aluminum. By A. W. McREYNOLDS | 32 |
| Discussion | 876 |
| On the Structure of Gold-silver-copper Alloys. By J. G. McMULLIN and J. T. NORTON | 46 |
| Discussion | 857 |
| Stress and Strain States in Elliptical Bulges. By C. C. CHOW, A. W. DANA, and G. SACHS | 49 |
| A Study of Textures and Earing Behavior of Cold-rolled (87-89 pct) and Annealed Copper Strips. By MING-KAO YEN | 59 |
| Discussion | 887 |
| Use of Electrical Resistance Measurements to Determine the Solidus of the Lead-tin System. By R. HULTGREN and S. A. LEVER | 67 |
| Discussion | 859 |
| The Effect of Strain-temperature History on the Flow and Fracture Characteristics of an Annealed Steel. By E. J. RIPLING and G. SACHS | 78 |
| The Densification of Copper Powder Compacts in Hydrogen and in Vacuum. By C. B. JORDAN and P. DUWEZ | 96 |
| Discussion | 893 |
| Influence of Composition on the Stress-corrosion Cracking of Some Copper-base Alloys. By D. H. THOMPSON and A. W. TRACY | 100 |
| Discussion | 862 |
| The Effect of Orientation Difference on Grain Boundary Energies. By C. G. DUNN and F. LIONETTI | 125 |
| Discussion | 860 |
| Solubility Relationships of the Refractory Monocarbides. By J. T. NORTON and A. L. MOWRY | 133 |
| Discussion | 891 |
| Pressure Distribution in Compacting Metal Powders. By P. DUWEZ and L. ZWELL | 137 |
| Discussion | 888 |
| Preferred Orientation in Rolled and Recrystallized Beryllium. By A. SMIGELSKAS and C. S. BARRETT | 145 |
| Discussion | 886 |
| Magnesium-lithium Base Alloys—Preparation, Fabrication, and General Characteristics. By J. H. JACKSON, P. D. FROST, A. C. LOONAM, L. W. EASTWOOD, and C. H. LORIG | 149 |
| Discussion | 867 |
| Self-diffusion in Sintering of Metallic Particles. By G. C. KUCZYNSKI | 169 |
| Discussion | 896 |
| Homogeneous Yielding of Carburized and Nitrided Single Iron Crystals. By A. N. HOLDEN and J. H. HOLLOMON | 179 |
| Discussion | 877 |
| The Surface Tension of Solid Copper. By H. UDIN, A. J. SHALER, and J. WULFF | 186 |
| Discussion | 894 |
| Properties of Chromium Boride and Sintered Chromium Boride. By S. J. SINDEBAND | 198 |
| Discussion | 889 |
| The Hardenability Effect of Molybdenum. By J. M. HODGE, J. L. GROVE, and R. G. STORM | 218 |
| A Method of Examination of Sections of Fine Metal Powder Particles with the Electron Microscope. By LAURENCE DELISLE | 228 |
| The Effect of Ferrite Grain Size on Notch Toughness. By J. M. HODGE, R. D. MANNING, and H. M. REICHHOLD | 233 |
| Recrystallization and Microstructure of Aluminum-Killed Deep Drawing Steel. By R. L. RICKETT, S. H. KALIN, and J. T. MACKENZIE, JR. | 242 |
| Precipitation Phenomena in the Solid Solutions of Nitrogen and Carbon in Alpha Iron below the Eutectoid Temperature. By L. J. DIJKSTRA | 252 |
| The Crystal Structure of Ni ₃ W. By E. EPREMIAN and D. HARKER | 267 |
| The Beryllium-iron System. By R. J. TEITEL and M. COHEN | 285 |
| Discussion, Institute of Metals Division, Fall Meeting, 1948 | 297 |
| Investigation of Temper Brittleness in Low-alloy Steels. By S. A. HERRES and A. R. ELSEA | 366 |

| | PAGE |
|--|------|
| Oriented Arrangements of Thin Aluminum Films on Ionic Substrates. By T. N. RHODIN, JR. | 371 |
| P-type and N-type Silicon and the Formation of the Photovoltaic Barrier in Silicon Ingots. By J. H. SCAFF, H. C. THEURER, and E. E. SCHUMACHER | 383 |
| Microstructures of Silicon Ingots. By W. G. PFANN and J. H. SCAFF | 389 |
| The Study of Grain Boundaries with the Electron Microscope. By J. F. RADAVICH | 395 |
| Transformation of Gamma to Alpha Manganese. By E. V. POTTER, H. C. LUKENS, and R. W. HUBER | 399 |
| Liquid Solubility of Manganese in a Magnesium-aluminum-tin Alloy. By B. J. NELSON and G. F. SAGER | 405 |
| The Comparative Creep Properties of Several Types of Commercial Coppers. By A. D. SCHWOPE, K. F. SMITH, and L. R. JACKSON | 409 |
| The Rapid Determination of Orientations of Cubic Crystals. By C. G. DUNN and W. W. MARTIN | 417 |
| The Vapor Pressures of Zinc and Cadmium over Some of Their Silver Alloys. By C. E. BIRCHENALL and C. H. CHENG | 428 |
| Electrical Resistivity Measurements on Iron-silicon Compacts Prepared by the Powder Metallurgy Procedure. By F. W. GLASER | 475 |
| A Metallographic Description of Fracture in Impact Specimens of a Structural Steel. By M. BAEYERTZ, W. F. CRAIG, JR., and E. S. BUMPS | 481 |
| Recovery and Recrystallization in Brass. By B. L. AVERBACH | 491 |
| Ferromagnetic Alloys in the Systems Cu-Mn-In and Cu-Mn-Ga. By F. A. HAMES and D. S. EPPELSHEIMER | 495 |
| Secondary Recrystallization in Copper. By M. L. KRONBERG and F. H. WILSON | 501 |
| Kinetics of the Reactions of Zirconium with O ₂ , N ₂ , and H ₂ . By E. A. GULBRANSEN and K. F. ANDREW | 515 |
| The Active Slip Systems in the Simple Axial Extension of Single Crystalline Alpha Brass. By R. MADDIN, C. H. MATHEWSON, and W. R. HIBBARD, JR. | 527 |
| The Effects of Molybdenum and Commercial Ranges of Phosphorus upon the Toughness of 0.40 Pct Carbon Chromium Steels. By M. BAEYERTZ, W. F. CRAIG, JR., and J. P. SHEEHAN | 535 |
| The Effect of Quenching on the Age Hardening of Two Aluminum Alloys. By R. D. BARER and M. B. BEVER | 544 |
| Determination of Boundary Stresses during the Compression of Cylindrical Powder Compacts. By M. E. SHANK and J. WULF | 561 |
| A Dilatometric Study of the Sintering of Metal Powder Compacts. By P. DUWEZ and H. MARTENS | 571 |

The Morenci Smelter of Phelps Dodge Corporation at Morenci, Arizona

L. L. McDANIEL,* Member AIME

COPPER smelters of various kinds have operated in the Morenci district since 1872, but all have been abandoned with the exception of the present Morenci Smelter of Phelps Dodge Corporation, which was completed in 1942.

During the five-year period starting in 1937, the Morenci ore body was prepared for open pit mining, pilot mill test work was carried out, and a complete reduction works, of which the Smelter is a part, was designed and erected. Actual construction work on the Morenci Smelter was started in the fall of 1940, and warming up of the units began on April 1, 1942. Charging of the reverberatory furnaces commenced on April 18, 1942, and the first anode copper was produced on April 26, 1942.

The smelter was originally designed to handle the production of the Morenci Concentrator on a 25,000 ton per day program, but by the time the smelter was in operation, plans were already underway to increase the smelter capacity to handle the production of the concentrator which was being enlarged to 45,000 tons a day capacity as a war-time necessity. This extension to the smelter was completed and the new units were put in operation toward the beginning of 1944.

The original smelter consisted of a smelter crushing plant, bedding plant, two direct-smelting reverberatory furnaces with two waste-heat boilers on each furnace, three converters, an anode department, a stack, and all of the usual accessory smelting equipment. The extension consisted of increasing the bedding plant from three to five beds, the reverberatory department from two to four furnaces, and from four to eight waste-heat boilers, and the converter department from three to six converters. A third converter aisle crane was added and additions were made to the flue systems and conveyor systems throughout the

smelter; but no change was made in the smelter crushing plant or the anode department, and the same stack was used for all additional Smelter units. A blister casting machine was installed at that time in the south end of the converter aisle to handle excess and emergency production above the capacity of the anode department and in 1947 a converter aisle skull breaker and a lime burning plant were added as the final units for a complete plant.

The choice of direct smelting over calcine smelting for the Morenci Smelter was made after careful study by members of the Western organization of Phelps Dodge Corporation and after test runs on direct smelting of Morenci concentrate had been made at the Douglas Smelter of Phelps Dodge Corporation. The Morenci furnace charge is made up of comparatively high grade concentrate with no ores of smelting grade available and with only flux, a small amount of copper precipitate and the usual amount of smelter secondaries to be smelted with the concentrate. The simplicity of direct smelting for this charge and the large amount of waste-heat steam available from direct smelting operations were factors influencing the decision to adopt direct smelting for Morenci. The design of the Morenci Smelter and the type of units selected followed best experience at the Douglas Smelter of Phelps Dodge Corporation.

A description of the original smelter before operations started was given in an article in the May 1942 issue of *Mining and Metallurgy*. The purpose of the present article is to describe the enlarged Morenci Smelter, with a discussion of metallurgy and operating

practice and to show tabulations of operating and metallurgical results obtained. Because of beginning operations during the early years of World War II, many problems caused by labor shortage were encountered, but no major difficulties developed in starting the new plant. However, because of labor shortage, full scale Smelter production was not reached until the fall of 1946.

Fig 1 shows a general plan of the Morenci Reduction Works. The arrangement of the smelter equipment is shown in Fig 2, a sectional view of the smelter is shown in Fig 3, and the smelter flow sheet is shown in Fig 4.

Metallurgy

The metallurgy of direct smelting, being more or less fixed by the character of the charge, is not subject to the control available in calcine smelting. Slags may be modified by the addition of suitable fluxes, but the grade of the matte is determined almost entirely by the iron:copper ratio of the concentrate.

The direct smelting operation involves distributing the wet concentrate along the sidewalls and in the bath of a reverberatory furnace by means of some suitable feeding device and raising the temperature of the charge so that first the moisture is driven off, then the first-atom sulphur is eliminated, and finally the sulphide portion of the charge melts and runs into the bath, carrying with it the non-sulphide portion which has been partially fluxed to form a suitable slag. The fusion of the non-sulphide portion is completed by contact with the iron converter slag which is regularly being poured into the reverberatory furnace. The smelting rate of the charge is influenced by the mineralogical composition of the sulphide portion of the concentrate and by the composition and amount of the non-sulphide portion including the fluxes added.

The copper in Morenci concentrate is chiefly in the form of chalcocite, intimately associated with pyrite, and non-sulphide content is very low so that

San Francisco Meeting, February, 1949.

TP 2488 D. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before April 1, 1949. Manuscript received at the office of the Institute June 1, 1948.

*Smelter Superintendent, Phelps Dodge Corporation, Morenci Branch, Morenci Arizona.

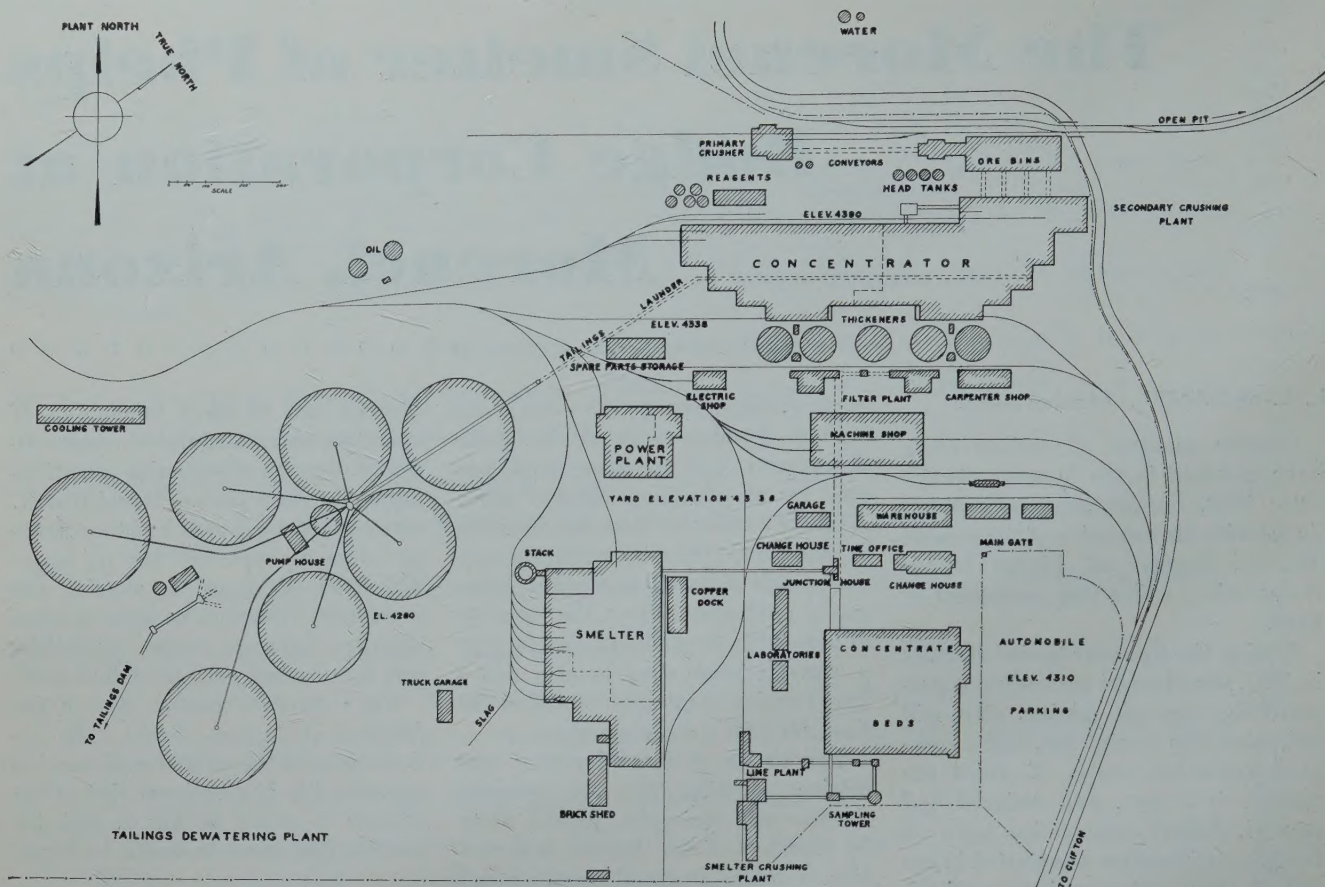

FIG 1—General plan of Morenci reduction works.

the main problem of the smelter is in fluxing and eliminating iron. The copper content of the Morenci concentrate increased appreciably, and the iron content decreased during the first few years of operation. Smelter metallurgy improved correspondingly as the iron burden was lessened and the converters were relieved of part of their work. The concentrate is graded upward 7.0 to 8.0 units of copper in forming matte, the amount being influenced somewhat by the quantity of precipitate on the charge.

There is no metal bearing siliceous flux readily available in the Morenci district and ore from the Open Pit mining operation is too high in alumina to be used alone. It has been necessary therefore, to mine a barren quartzite for use in modifying furnace slags. This is also used in adjusting the silica: alumina ratio of the Pit ore used for converter flux to prevent the formation of excessive amounts of magnetite in converter slags. Limerock is used to flux the non-sulphide content of the concentrate, and at times, additional limerock and quartzite are added to the bedded concentrate to reduce the moisture content of the furnace feed.

The make-up of the furnace charge

is usually quite uniform although at times other material has been smelted. In 1943 and 1944 a large amount of clean-up material from an old smelter in the district was crushed and smelted in the reverberatory furnaces, and during early operations at the smelter a large quantity of reverts accumulated in the converter aisle which eventually were crushed and smelted with the reverberatory furnace charge. At the present time most of the converter reverts are smelted directly in the converters and any excess is crushed and added to the converter flux to modify the high silica content resulting from the use of barren quartzite. Foul slag from the reverberatory furnaces is also crushed and added to the converter flux

for this purpose. Crushing of reverts and foul slag is done simultaneously with the barren quartzite to insure a good mixture.

The dry weight of concentrate received at the smelter is calculated by the concentrator from actual weightometer weights of feed to the ball mills and assays of automatic samples of feed, tailings and concentrate. This method has been very reliable over a considerable period of time. The moisture content of the concentrate is determined by sampling as the concentrate leaves the filter plant.

Smelter slag, stack and mechanical losses are shown in Table 1. Stack loss tests are made regularly and reverberatory slags are sampled at the furnace

and on the dump. Anode copper is weighed and sampled at the refinery for final settlement.

Results have shown that direct smelting of Morenci concentrate has proved successful with a concentrate grade above 25.0 pct copper and an iron:copper ratio of about 1.00, and that smelter equipment and arrangement have been satisfactory. Production figures for the total plant are shown in Table 2. In all tabulations in this paper figures for 1946 are based on 8.4839 months operating time because of a general strike in the industry which caused a shut-down that year.

Smelter Crushing Plant and Lime Burning Plant

The smelter crushing plant was designed to crush Pit ore and siliceous ore for converter flux and limerock and siliceous ore for reverberatory flux, as well as smelter reverts and miscellaneous material required in smelter operations. The crushing plant was also designed to crush limerock for a lime burning plant which is operated by the smelter organization to produce burned lime for the Concentrator.

In order to eliminate crushing of large sized material from open pit shovel mining operations, Pit ore

crushed to $\frac{3}{4}$ in. is drawn from the fine ore bins at the concentrator into 40 yd side dump railroad cars and hauled to the smelter crushing plant and then conveyed to converter flux bins in the bedding plant without further crushings. Barren quartzite is mined in a quarry near the Reduction Works and trucked to the smelter crushing plant. Truck haulage is to be replaced by rail haulage at a later date. Limerock is mined in a quarry near the Open Pit Mine, trucked for a short distance, and loaded into side dump railroad cars for haulage to the smelter crushing plant.

The 100-ton receiving bin in the smelter crushing plant is served by railroad cars or trucks and the material is fed by a 48-in. pan feeder directly into a 36- \times -48-in. jaw crusher. The 4-in. product of the jaw crusher passes over a 5- \times -10-ft mechanically vibrated rod deck screen with $1\frac{1}{2}$ -in. opening, the oversize feeding directly

into a 7-ft standard cone crusher with $1\frac{1}{4}$ -in. setting. This loose setting is required because of crushing smelter reverts containing metallic copper. The combined product of the 7-ft standard crusher and screen passes over another 5- \times -10-ft rod deck screen with $\frac{1}{4}$ -in. opening, the oversize falling into a 4-ft shorthead cone crusher which is in closed circuit with the screen.

In the case of Pit ore and siliceous ore used for converter flux the material by-passes the 4-ft shorthead crusher and goes directly to the 5,000 ton storage bins at the end of the bedding plant. Limerock for flux and other material which is crushed to $\frac{1}{4}$ in. in the shorthead crusher may be delivered either to sections of the storage bins or directly to the beds. The material leaving the crushing plant is sampled by an automatic sampler in a sample tower, which takes a 10 pct cut. The material so far sampled has been barren flux and

FIG 3—Sectional view of smelter.

no information has been obtained on operation of the sampling equipment.

Limerock for the lime burning kiln by-passes the shorthed crusher and is delivered to a 5- \times 10-ft rod deck screen with $\frac{1}{4}$ -in. opening in the sample tower, from which the under-size goes to the bedding plant storage bins and the oversize goes to the lime burning plant 1,000-ton capacity storage bin. Limerock from this storage bin is delivered by belt conveyor to the 275-ft rotary lime burning kiln which is fired with natural gas and produces 100 tons of burned lime per day.

A lime hydrating plant using a ball mill and classifier for preparation of milk of lime for the Concentrator ad-joins the smelter crushing plant and receives burned lime from the 900 ton storage bin at the discharge end of the lime kiln. Milk of lime is pumped to the Concentrator through a 10-in. pipe.

The smelter crushing plant, sample tower, lime plant and storage bins are provided with dust control systems using wet collectors for the exhaust from the fans.

Bedding and Reclaiming Plant

The bedding plant serves a two-fold purpose: (1) It smooths out daily variations in concentrate composition so that furnace metallurgy and matte grade will be more uniform and, (2) it provides storage capacity to take care of interruptions to operations in either the Smelter or the Concentrator.

There are five beds, completely enclosed to prevent wind losses. The beds are 66 ft wide and 300 ft long with an effective bedding area of 50 \times 250 ft which gives a capacity of 5,000 tons of concentrate each. Concentrate from the filter plant is delivered by two conveyor belts in parallel onto cross-

conveyors over each of the beds where the concentrate is automatically distributed from one end of the bed to the other by motor driven tripper cars. After a bed has been completed and analysis made, the proper amount of limerock and siliceous ore flux is removed from the storage bins and diverted by means of a shuttle conveyor in the junction house, which is a distribution point, to one of the conveyors from the filter plant. The flux is delivered from this conveyor to the overhead conveyor above the bed and distributed over the concentrate on the bed. Flux may also be diverted directly from the smelter crushing plant to the cross conveyors over the beds. A bin in the junction house is provided with a belt feeder to handle copper precipitate and cleanup material from the smelter and feed it onto the concentrate conveyor delivering to the beds. Flue dust from a pug mill is also added to this conveyor in the junction house.

The final bedded mixture of concentrate and flux is removed by a reclaiming machine working into one end of a bed and plowing across the face and delivering the mixture onto a belt conveyor in a trench along the side of the bed. The reclaiming rate is about 150 tons per hr. There are two reclaiming machines which can be moved to any bed by means of a transfer car. This method of bedding and reclaiming furnace charge provides great flexibility in fluxing the charge and results in a very nearly perfect mixture of the charge for the furnaces.

The furnace charge, which is dropped on the trench belt by the reclaiming machine, is delivered through the junction house onto an inclined belt conveyor which transports the material across the converter aisle to a cross conveyor and then to two 265-ton bins above each reverberatory furnace.

Small sections of these bins are also used for siliceous material for fettling. The same conveyor belt system is used to remove converter flux from the storage bins and deliver it to 250-ton bins above each converter. Clay for a mud mill and quartz for a slurry mill are also delivered to bins on the reverberatory floor by this belt system.

Twenty-inch conveyor belts are used on all overhead receiving conveyors and 24-in. conveyor belts are used on the reclaiming system delivering material from the beds to the smelter. All belt conveyors are provided with dust collecting systems at transfer points in the junction house and at the top of the smelter building. In addition, the conveyor gallery above the converter flux bins is kept under slight pressure by a ventilating system delivering 75,000 cfm of fresh air, which keeps the gallery free from smoke and reduces temperature for the comfort of workmen and protection of the conveyor belting. A similar installation in the conveyor gallery over the reverberatory furnace bins discharges 100,000 cfm of fresh air.

Reverberatory Furnaces

The four direct-smelting reverberatory furnaces are located on a block of unexcavated ground 15 ft above the surrounding yard level. Furnace foundations are formed of heavy, re-inforced concrete in a monolithic band around the furnace. Concrete beams were placed between the furnaces, which are on 70-ft centers, and the outer walls of the foundations on No. 1 and No. 4 furnaces were carried downward an additional 8 ft to prevent bending of the longitudinal sections by expansion pressures.

After the concrete foundations for the furnaces were poured and the rods for the end steel bindings were in place

slag bottoms were poured in the furnaces to seal the conglomerate subsoil and to anchor the end steel bindings. Slag for the first two furnace bottoms was melted in a small natural-gas fired reverberatory furnace located between the two furnace foundations. An abandoned reverberatory furnace at an old smelter in the district was dismantled and the brick and steel were used to build the 14 × 50 ft slag melting furnace. Crushed blast furnace slag was obtained from a slag dump from previous operations in the Morenci District and the slag was hauled to the furnace site in trucks and charged into the small furnace with a grab bucket on the boom of a motor crane. Slag was tapped in about 30-ton lots into launders leading into the furnace bottoms. The depth of slag poured in the end sections of the bottoms was 8 ft and in the middle sections 4 ft. The slag remained partly liquid underneath the crust between pours and the final block of slag was dense and relatively free from cracks. About 1200 tons of slag was poured in each bottom. Slag for the bottoms of the last two reverberatory furnaces constructed, No. 3 and No. 4, was run directly from No. 2 reverberatory furnace through launders to the new furnace bottoms.

An attempt was made to fuse in the final furnace bottoms for the first two furnaces with 24 in. of crushed silica at the time the furnaces were started up. However, as soon as charging of the furnaces began, the silica bottoms in both furnaces came up and were lost. The bottoms floated shortly after charging was started and as soon as sufficient matte had accumulated to penetrate beneath the bottom and force it up.

The loss of the silica bottoms occasioned no serious delay to operation, and it developed that the furnaces operated very satisfactorily without the silica bottoms and with a deep bath of matte resting directly upon the original slag bottom that was poured into the furnace at the time the furnaces were constructed. There was no noticeable effect on the furnace foundations from the deep bath of matte, and the bath of matte actually aided in smelting the charge. It was therefore decided to build the two new furnaces, No. 3 and No. 4, without silica bottoms and with the poured slag bottoms at approximately the same elevation as in the first furnaces, that is, about 24 in. below the matte tap holes. This was done and these slag bottoms in all fur-

naces have been very successful. However, the deep bath of matte below the tap hole has not proved advantageous over a period of time because of lack of circulation of the matte. The bottom soon fills up with magnetite to the elevation of the tap holes and it is therefore the present practice when digging out a furnace to leave the bottom at an elevation only a few inches below the tap hole.

Structural details of the furnaces are shown in Fig 5. The furnaces measure 31 ft 3 in. × 110 ft 0 in. from face to face of buckstays and 25 ft 6 in. × 102 ft 6 in. inside the brickwork at the normal slag line. All steel bindings are of exceptionally heavy construction.

The furnace arches, sidewalls and endwalls are made of silica brick. The bridgwall and front walls are faced with chemically bonded magnesite brick and there is a band of magnesite brick completely around the furnace walls, constituting a crucible below the metal line. The furnace uptakes and cross-overs to the boilers are largely of suspended brick construction, with high alumina fire brick in the walls and magnesite brick in the arches. Dampers of light weight insulating brick and alloy steel construction are suspended above the cross-overs for use between the furnace and the boiler.

The 20 in. silica brick arches of the reverberatory furnaces have shown

good life under direct smelting conditions, and all of the original arches were still in place at the end of the first 4½ yr of operation, with No. 2 and No. 3 furnaces each having smelted around 400,000 tons of charge and No. 1 furnace, 600,000 tons of charge at that point. Furnace campaigns average 2 to 2½ yr and major repairs consist of digging out the bottom by blasting and slushing and making repairs to brickwork in the bridgewall, sidewalls, front wall and uptakes and cross-over arches. In the future, greater repairs to the main arches are anticipated because of greater length of service. All silica arches and sidewalls are maintained by the slurry gun patching method developed at United Verde Branch of the Phelps Dodge Corporation. A slurry preparation plant using a 6 × 12 ft ball mill is located at the north end of the reverberatory floor.

Furnace charge is removed from the 265-ton bins above each side of the furnace by 54-in. pan feeders which discharge into drag chain conveyors. The conveyors are 80 ft long with spring gate openings in the box every 4 ft which discharge into hoppers and then into 8-in. charge pipes leading into the furnace.

The furnaces originally were equipped with vibrating conveyors, which worked satisfactorily as long as the moisture content of the charge did not exceed the critical point of the vibrators. The moisture content of the concentrate from the filter plant is considerably higher than this point and

even after it is lowered by flux additions and by some drying on the beds, the moisture is still close to the critical limit; and when this limit is exceeded trouble is encountered with the vibrators. For this reason the decision was made to replace all vibrating conveyors with drag chains, but because of delay in delivery of material for full length drag chain conveyors it was necessary to make the installation in two stages, the first being short sections of drag chain under the pan feeders which delivered onto the remaining sections of vibrating conveyor. Electrical controls for drag chains and other furnace equipment are housed in two control rooms 15 ft above the floor level.

The furnaces are usually charged four or five times a shift, the charge being distributed evenly over the charge banks from both drag chains simultaneously. It is desirable to have some of the charge run out into the bath in the center channel of the fur-

nace, thus exposing greater area to the combustion flame and to the hot bath in the furnace and providing better contact with liquid converter slag for the reduction of magnetite. If the wet charge in the bath becomes too heavy, it is forced down through the slag and comes in contact with the matte and an explosion occurs. Mild explosions are normal and are desirable because they tend to bring more of the charge in contact with the hot bath, which increases the smelting rate; but at times the explosions may be rather violent and may be hazardous to men working around openings in the furnace or boilers and may cause damage to furnace arches. It is the practice at Morenci to attempt to minimize the force of the explosions by keeping the charge banks well filled so that too much charge does not run out into the bath in one place. It is also the practice to keep tie rods tight and to use steel props on the arch to prevent movement.

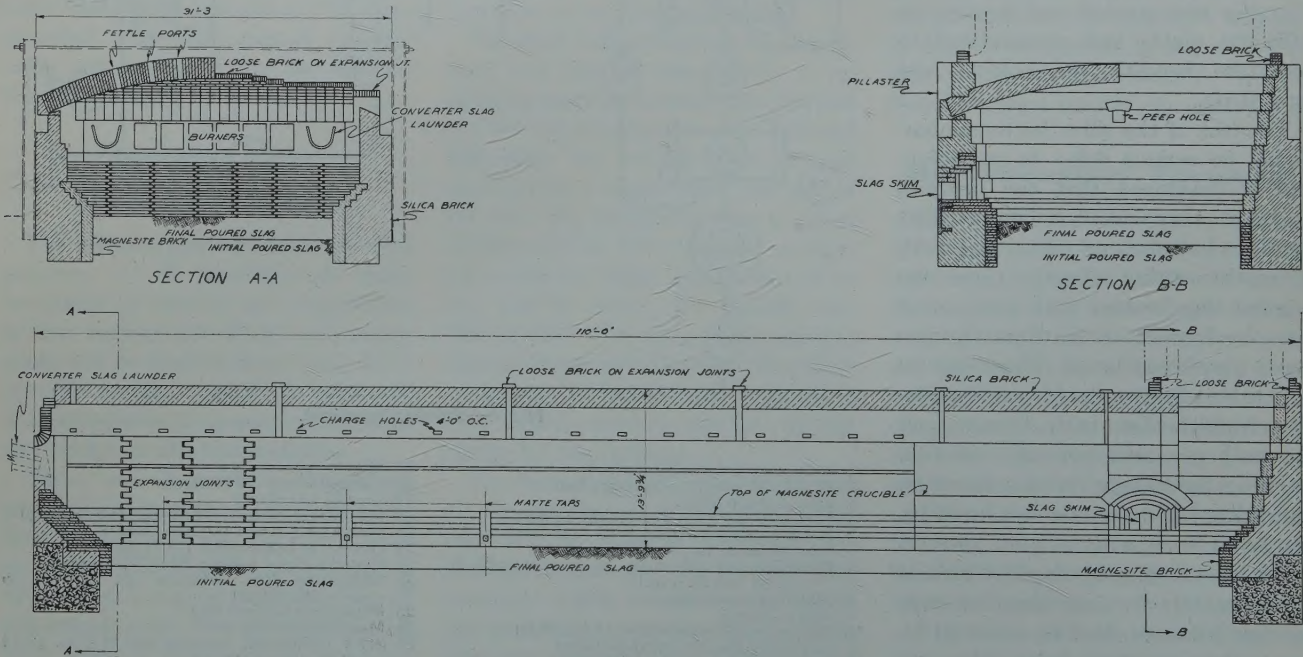

FIG 5—Longitudinal and cross-sectional views of reverberatory furnace brickwork.

The reverberatory furnaces are fired with natural gas and originally were equipped with eight panels of multiple jet burners on each furnace, spaced across the bridgewall with suspended arch construction above the burners. These burners gave satisfactory results, provided the capacity of the burner was not exceeded, but the burners were very difficult to keep clean because of the explosions in the furnace which plugged the burner ports with charge and slag and made control difficult. For this reason and also in order to improve combustion efficiency at higher rates of gas burning a change was made to high pressure burners which enter the bridgewall through large pipes. With large pipes there is less tendency for the burners to become fouled during explosions and combustion control and efficiency are better. The high pressure burners cause somewhat greater arch corrosion as a result of greater turbulence in the combustion zone, but this is not serious and simply requires greater attention to arch maintenance with the slurry gun.

Natural gas from the New Mexico fields is delivered to the plant by pipe line under 300-lb pressure and is then reduced to suitable pressure for use as fuel in the reverberatory furnaces and boilers. Stand-by fuel oil equipment including heaters, pumps and steam atomizing burners has been provided for emergency use and has been used a few times during interruptions to natural gas deliveries.

The natural gas contains about 1100 Btu per cu ft and gas pressure at the burners averages 37 psi, controlled by very sensitive pilot loaded regulators. About 140,000 cfhr of gas is burned in each furnace. Furnace combustion is controlled by frequent analysis of combustion gases with an Orsat apparatus on day shift at a sampling point 75 ft from the bridgewall. Close control of furnace draft is essential to proper combustion and the draft is regulated by automatic dampers back of each waste-heat boiler. Secondary air is largely excluded from the furnace, although some secondary air infiltration is unavoidable and is used to complete the combustion of the natural gas and to burn a small amount of elemental sulphur. No attempt is made to provide excess air for the complete combustion of volatilized first-atom sulphur, as calculations indicate this to be uneconomical. Some sulphur vapor is burned in the furnace, furnace uptakes and boilers, however.

Table 4 . . . Analysis of Reverberatory Solid Charge

| | Au | Ag | Cu | SiO ₂ | Al ₂ O ₃ | Fe | CaO | S | H ₂ O |

Some trouble has been encountered with magnetite building up in the reverberatory furnace bottoms. The only source of magnetite is through converter slag additions to the reverberatory furnace, but control of magnetite at the converters is difficult because of the high alumina content of the converter flux. Magnetite in the bath of the reverberatory furnace is partly reduced by contact with sulphides and if free silica is available to combine with the resulting ferrous oxide, magnetite can be fairly well controlled. If free silica is introduced with the charge the smelting rate of the charge is affected adversely and a practice has been

each bed and amounts to 70 to 75 pct of the solid charge, or 80 to 85 pct of the concentrate smelted. Matte is tapped through either of three tap holes on each side of the furnace at the bridgewall end, opposite tap holes being used on alternate shifts to allow time for cleaning launders. The matte runs through brick and clay lined launders into 200-cu ft cast steel ladles in the Converter aisle. Two wet pan mills for the preparation of clay for stoppers and launder lining are located at the north end of the reverberatory floor.

Furnace slag is removed from the side of the furnace near the uptake end,

worked out of introducing barren quartzite through the arch of the furnace about 20 ft from the bridgewall so that two piles of quartzite, one on either side of the centerline, are maintained floating on the bath in front of the converter slag launders which enter through the bridgewall on each side adjacent to the junction between the sidewall and the bridgewall. By this means free silica is made immediately available when converter slag is introduced and the smelting rate of the charge is not interfered with. This practice has resulted in marked improvement in the control of magnetite and in the protection of furnace bottoms.

A deep bath of matte is carried in the furnace at all times unless prevented by high furnace bottoms. Matte-fall is quite uniform throughout the life of

the slag skim hole being located just back of the verb arch. The slag is skimmed into 225-cu ft cast steel pots and hauled to the dump by 18-ton electric trolley locomotives. Slag-fall amounts to 65 pct of the solid charge or 75 pct of the concentrate smelted. The slag dump is trimmed and leveled with a bulldozer and the track is thrown with a mechanical track-shifter.

Reverberatory furnace data are shown in Tables 3, 4, 5, 6 and 7.

Table 7 . . . Analysis of Reverberatory Matte

Waste-Heat Boilers

Waste-heat boiler practice with the large water wall area and high steam pressure and temperature has been satisfactory. There are two waste-heat boilers on each reverberatory furnace and each boiler has 11,430 sq ft of total heating surface. Steam is produced at 700 lb ga. pressure and 700°F temperature. The boilers operate at over 100 pct of rating and waste-heat steam produced amounts to 40,000 lb per boiler per hr, which represents a recovery of 53.0 pct of the fuel fired in the reverberatory furnaces.

Combustion gases from the reverberatory furnaces pass through the waste-heat boilers as shown in Fig 2 and 3. The three-drum boilers have internal pendant type superheaters and are equipped with soot blowers using superheated steam on all banks of tubes. The soot blowers are used every 4 hr and are effective in cleaning areas where no sintering or slagging of the dust occurs, but all boilers require complete hand lancing with high pressure air pipes through small ports to remove sintered and caked dust not touched by the soot blowers and to remove slag which forms on the tubes in the area of the boiler inlet from the furnace. Automatic soot blowers on water wall tubes are being considered as a means of lessening hand lancing.

The boiler settings are of fire brick construction with special shapes to fit the water wall tubes. The boiler baffling is shown in Fig 3 and the boilers operate with a draft loss of 0.80 in. of water through the boiler. The cross-over connecting flues between the reverberatory furnaces and the waste-heat boiler were made as short as possible to reduce radiation losses. The boiler structures are quite high and this resulted in a stack effect for incoming gases and a back pressure which made an unsatisfactory smoke condition around the boilers. This condition has been overcome by restricting the outlet of the reverberatory furnaces with dampers so that the back pressure in the boilers can be neutralized without upsetting the furnace draft.

Converters

The arrangement of the converter aisle is shown in Fig 2. The aisle is 63 ft wide and 574 ft 6 in. long, with crane rails 57 ft 6 in. above the ground and a span of 60 ft between crane rails. The three cranes each have two 60-ton hoists driven by 100 hp direct-current

motors with magnetic brakes on the motor shaft and gear train. Two 5-ton repair hoists and one 50-ton repair hoist are located above the crane runway.

There are six 13- × 30-ft Pierce-Smith converters located on 60-ft centers. The converter shells are 1½ in. steel plate, welded construction with heavy reinforcing plates along the tuyere section and around the mouth. The welded steel riding rings are riveted to the shell at the outer ends of the shell. The converter ends are made of 1 in. welded plate with 4 beam stiffeners on each end and the ends are held in place by bolts and springs to allow for expansion. The springs have been of value in relieving expansion after repairs, but a point is reached where the springs cannot be used without digging out the entire end sections of the converter and re-setting the end plates in their original position.

The converters are driven by 75 hp dc motors with magnetic brakes, through a speed reducer, intermediate gears and pinion and large gear which is bolted to one of the riding rings. Direct-current for operation of converters, cranes, anode furnaces, and slag locomotives is generated by two 600 kw fly-wheel motor-generator sets and one 300 kw stand-by motor-generator set located in control rooms behind the converters. If the direct current generators and the turbo-blowers in the power house are put out of service by a power failure, the fly wheels can furnish sufficient power to turn down the converters and to allow the cranes to be moved. A signal on the converter air main sounds an alarm when the air pressure drops below a pre-determined point.

The converters have 52 ball valve tuyeres with threaded connections arranged so that 10 tuyeres on each end have 2-in. tuyere pipes and the 32 tuyeres in the center have 1½-in. tuyere pipes. There are two Garr guns, one on each end, for flux which is drawn from overhead bins of 250 tons capacity for each converter into 5-ton

measuring hoppers at each Garr gun. The Garr guns are used alternately to even the wear on the brick lining.

In normal operation, the converters are charged with 5 ladles of matte, amounting to about 70 tons, and additional matte is added after fluxing, blowing and skimming. Air pressure of 13 lb at the converter tuyeres has been found best for converter operation. Air volume averages 23,000 cfm at the tuyere with periods of 25,000 cfm. Air consumption is measured by indicating and recording meters on the 24-in. air line leading to the blast gate and wind box on each converter. An electrical signal system between the converter aisle, the power house, and the smelter office indicates and records the blowing time of each converter and shows which converters and which blowers are in operation at any time.

In making copper charges, matte is blown to white metal in two converters and the white metal from one converter is then transferred to the other and the copper charge finished in that converter. Copper charges average 90 tons and the copper is blown to "worm" copper for the anode plant. Oxide slag is formed in the converter at this stage of the blow and this slag is very corrosive on the brick lining and must be handled with care to prevent explosions when it is skimmed and transferred to another converter. After each transfer or charge of copper is completed the tuyeres are reamed with a cutter bar clamped in a light rotating drill which is supported by hand. This method of reaming tuyeres is much easier on the brick work than the use of a sledge hammer and cutter bar.

Converter campaigns between tuyere line repairs average 9000 tons of copper. No magnetizing of converter linings has yet been practiced. Hard burned chrome-magnesite brick is used in converter linings and repairs are made with the 18-in. four-piece tuyere block shown in Fig 6. The normal repair includes a number of courses in 18-in. wedge brick above and below the tuyere blocks and it is usually necessary

to extend the repair to include the arches at the back of the collar, and occasionally necessary to dig out and brick a section in the bottom or front of a converter. Spalling after repairs is avoided entirely by allowing proper expansion joints and by heating the converter very slowly with gas burners for about 48 hr until the entire brickwork is practically at operating temperature and then washing the converter with slag to seal the joints, and charging with matte while the converter is still near maximum temperature. The pouring lips on the converters are made with magnesite brick held in place by rails and grouted with magnesite ganister. The space between the 1-in. apron plate and the shell below the pouring lip is boxed in and filled with magnesite ganister to prevent metal leaks around the brick pouring lip.

Converter hoods are of welded steel construction with cast iron liners in the lower portion. The hood gate rolls on rails and is raised and lowered by motor driven sprockets and chains. A butterfly damper in the circular section of the

converter uptake flue is operated by high pressure air with control valves on the skimmer's platform.

Converter puncher's platforms are raised and lowered for adjustment by hydraulic lifts using oil pressure, and each platform has an air cooling system of overhead ducts with slots for blowing low pressure air from individual motor driven blowers. Stationary platforms behind the converters connect all punchers platforms and also connect with the skimmers platforms.

Converter cleanings, hood cleanings and dust from the hoppers back of the converters are collected in boats on wide gauge cars which are pulled backward behind the converters onto a transfer car running parallel to the converters and reaching the converter aisle under the cranes at the south end of the aisle. The transfer car track is directly underneath the dust hoppers behind each converter and dust is easily drawn into the cars as they are pulled from under the converters. The cleanup in front of the converters is done with a weighted drag handled by the converter crane, and a Traxcavator is used for loading the cold material into boats. Matte and slag ladles are shelled into a skull breaker with an elevated bumping block in the south end of the converter aisle; and cold material from the skull breaker is hauled to the smelter crushing plant in railroad cars.

Converter data are shown in Tables 8, 9, 10, 11 and 12.

All Morenci copper is produced as anode copper for economy at the refinery. The anode plant is located at the north end of the converter aisle as shown in Fig 2 and contains two refining furnaces of the same type as the converters, but with shells 13 × 25 ft instead of 13 × 30 ft, and one casting wheel. Anode plant practice with rotating furnaces is entirely satisfactory and the arrangement of two refining furnaces and one casting wheel provides flexibility and storage capacity for uniform converter operations.

The anode furnace shells are made of 1½-in. plate, welded construction, with riding rings at the ends and with openings for the poling and skimming door and casting spout. The ends of the vessels are made of 1-in. welded plate with reinforcing beams which are fastened rigidly to the shell. The ends have openings for the receiving spout, burner port and stack outlet. The direct current motors and gear drives are duplicates of those used on the converters.

The anode furnaces are heated with natural gas in burners using high-pressure air for short flame combustion. The burner enters through one end wall well above the metal line. Anode charges average 175 tons of copper and two converter charges usually fill an anode furnace. The anode charges are blown with high-pressure air using two ¾-in. pipes to eliminate the sulphur, the slag is skimmed off and the copper is poled with oak or pine poles which are manipulated with an air operated hoist. The anode furnaces are surrounded by a large concrete platform at an elevation 2 ft below the centerline of the furnaces which provides working space for the blowing, skimming and poling operations.

Copper is poured from the anode furnaces into hydraulically operated pouring spoons and then into copper molds on a circular casting wheel 40 ft in diam with 26 molds. The wheel is electrically driven through gears by duplicate motors which turn the wheel in either direction. All operating controls for the anode vessels, pouring spoons, and casting wheel are located in cabs at each side of the casting wheel. The wheel is moved by an automatic timing device which controls the rate of casting; and the wheel stops automatically with one mold in proper position under the pouring spoon and another mold in proper position for lifting the anode

FIG 7—Anode furnace brickwork.

from the mold by tongs. Pouring speed averages 30 tons per hr.

The liquid copper poured into the mold from the spoon must chill on the surface before the casting wheel is moved to prevent rolled edges and fins on the anodes; and a blast of converter air automatically controlled by a solenoid valve, is used to speed up the cooling of the surface of the anode. Water cooling of the molds and anodes is accomplished by spray pipes at definite locations on the wheel. The empty molds on the casting wheel are sprayed inside while hot with an alumina sand wash to keep the anodes from adhering to the mold.

The anodes, which weigh 700 lb, are raised from the molds by pins with sliding contact on an inclined track,

and are lifted from the pins and placed in bosh tanks by manually operated air tongs with control valves at the side of the bosh tanks. Anodes are removed from the bosh tank by a 15-ton crane, inspected and trimmed on the floor adjacent to the anode plant and are then loaded into railroad cars by 2-ton storage battery trucks with vertical lift arms. A large concrete floor across the track from the anode floor is used as a copper dock for storage of anodes during periods of interrupted shipments. This floor and the trimming floor is armored with cast iron grids cast in the concrete.

Pouring spoons are lined with a cement-sand mixture. The spoons and cast iron master molds are heated to the proper temperature for use by indi-

vidual gas burners. Copper molds for the casting wheel and copper tapping plates for the reverberatory furnaces are made on day shift. The copper molds last for about 300 tons of anodes each before cracking too badly to use. One or two new molds are put on the wheel daily and the discarded molds are returned to the converters for smelting with the copper charges.

Anode furnace lining is shown in Fig 7. The chemically bonded magnesite brick has given excellent service and no major repairs to the brick lining have been made in the first six years of operation. Brickwork over the poling doors and around the openings in the ends of the furnaces is maintained by slurry gun patching with magnesite cement when required. The complete

insulation of the shells is desirable for fuel economy and for better working conditions and to prevent filling up of the bottoms with refractory slag.

Anode Plant data are shown in Table 13.

Flues and Stack

The entire flue system in the Morenci Smelter is of steel construction well insulated to prevent heat loss, and of large cross-sectional area to reduce gas velocities. Arrangement of the flue system and stack is shown in Fig 2. The steel balloon flue located back of the converters turns at right angle and rises in a vertical box connection to cross the converter aisle above the crane runway. Gases pass from this flue through mechanical dust collectors consisting of 10 sections of 16-in. Multiclone tubes, and then to the stack. The converter

flue is 18 ft in diam and is covered with 2 in. of fiber glass insulation from a point near the first converter to the dust collectors. The flue immediately back of the converters is not insulated. The mechanical dust collecting system is insulated and also the 18-ft balloon flue leading from the dust collectors to the stack.

A 15-ft steel balloon flue for reverberatory furnace gases, also insulated, leads from the waste-heat boiler outlets and joins the converter flue just in front of the portal of the stack. There is an automatic damper in the reverberatory flue which is operated by a motor

driven worm gear actuated by an electric eye connected to a draft gauge. The necessity for a dust collecting system on the reverberatory gases has not yet been determined.

The stack was built of reinforced concrete with a lining of acid proof brick laid in acid proof mortar and with insulation between the concrete shell and the lining. The stack is 603 ft 2 in. high, with a foundation 9-ft thick and 71 ft in diam standing on a consolidated conglomerate earth foundation with a loading strength of 5 tons per sq ft. The stack was designed to withstand a wind pressure of 100 mph. It is protected by lightning rods with copper cables to the ground. The inside diameter of the stack is 39 ft at the bottom and 24 ft at the top. The concrete shell is 36 in. thick at the bottom and tapers to 7 in. at the top. The total weight of the stack and foundation is about 10,000 tons.

The stack was designed for a draft of 3 in. of water with gases at 500°F and an outside temperature of 60°F and has a total capacity of 1,000,000 cfm at stack conditions. The high stack draft is necessitated by the use of mechanical dust collectors on the converter gases which operate with a pressure drop of 2 in. water. The remaining draft is lost in friction and at the converter hood openings.

The stack was built with two portals, one main portal and a smaller one directly opposite. The smaller portal has been bricked up and will be used only in case it is desired to divert part of the gases through a dust collecting system on the opposite side of the

FIG 8—General view of reduction works.

FIG 9—View of reclaiming machine.

FIG 10—View of reverberatory furnace skimming end.

stack. A test station is located 274 ft above the ground for testing stack gases.

Flue dust handling is accomplished mechanically by means of drag chain conveyors in the bottom of the balloon flues and screw conveyors under the multiclones. The granular abrasive dust from the balloon flue immediately back of the converters however is returned to the converter dust hoppers by gravity through 10-in. pipes at each hopper. The combined dust from the balloon flues and multiclones is collected in a surge bin and is then removed by a short screw feeder, mixed with air and pumped pneumatically to a pug mill located near the junction house through which pass the conveyor belts carrying concentrate from the filter plant to the bedding plant. The flue dust in the pug mill is sprayed with water until properly conditioned and is then discharged onto the layer of concentrate on the belt conveyor and delivered along with the concentrate to the bedding plant.

Power Plant

The Power Plant, which is under separate supervision, is situated about 500 ft from the waste-heat boilers. Steam from the waste-heat boilers at 700 lb pressure and 700°F temperature is delivered to two direct-fired superheaters in the power house, emerging from the superheaters at the proper condition for utilization at the turbine throttle, namely 650 lb ga. pressure and

825°F temperature. Three direct-fired water-wall boilers of 1430 hp each, using natural gas fuel with automatic burner control and air pre-heaters, and with stand-by fuel oil for emergency use, furnish additional steam which is combined with the waste-heat steam in the direct-fired superheaters. About 60 pct of the total steam is produced in the waste-heat boilers and 40 pct in the direct-fired boilers.

Steam is utilized in four 15,000 kva maximum capacity turbo-generators with surface condensers. Power is generated at 13,200 volts and is trans-

mitted to the Concentrator, Smelter, Open Pit mine and pumping stations at this voltage and is there stepped down to 2,300 volts and 440 volts for plant use. A very good power factor results from the use of a large number of synchronous motors in the Concentrator.

Condenser cooling water is pumped through concrete pipes to a cooling tower 1300 ft away. Evaporators are used for boiler feed water make-up and boiler feed water is deaerated, heated to 300°F and pumped to the waste-heat and direct-fired boilers by 8 stage electrically driven centrifugal pumps with steam pumps as stand-by. Waste-heat boiler feed water is delivered through 5-in. welded steel insulated lines with automatic control at the pumps and at the boilers. Steam is returned to the power house from the waste-heat boilers through two 10-in. welded steel insulated lines.

During periods of curtailed power requirement at the Open Pit Mine and Concentrator on scheduled week-end shut-downs, excess waste-heat steam is diverted to a separate condenser plant outside the power house. Cooling water for this condenser plant is circulated through the same system used for the condensers on the turbo-generators and condensate from the condenser plant is returned to the boiler feed water system.

Compressed air at 100 lb pressure is produced in two 3,730 cfm electrically driven compressors located on the ground floor of the power house. Con-

FIG 11—View of converter aisle.

FIG 12—View of anode plant.

verter air is produced by six electrically driven turbo-blowers of 27,500 cfm capacity each at 12.5 lb barometer and 100°F. The blowers are direct-connected to 1500 hp induction motors and operate at constant speed and pressure with automatic regulators controlling impedance vanes on the inlet air ports to adjust air volume to requirements. Converter air is produced at 14 lb pressure and 275°F at the blowers and the blowers discharge into a header pipe connected to a 60-in. air main leading to the converters. Air volume is

metered for each blower between the blower and the header pipe. (Fig 8-12)

Smelter Organization

Smelter operations are under the supervision of the smelter metallurgist, with a general foreman over the reverberatory department and another over the converter department. Shift operations in the reverberatory, converter and anode departments are under the supervision of shift foremen,

and the crushing, bedding and reclaiming plant, lime burning plant, brickmason crew, repair crew and labor crew are each under the supervision of a day shift foreman.

The Smelter maintains a technical staff for plant testing and investigation and a safety department which is a part of the Branch safety organization.

Smelter maintenance work is carried out by the smelter repair crew and brickmason crew, while heavier work is done by the well equipped shops at the Reduction Works.

The Interaction of Liquid Steel with Ladle Refractories

CARL B. POST* AND GEORGE V. LUERSSEN,* Members AIME

It is generally recognized that non-metallic inclusions in steel come from two principal sources. First are the chemical reactions in the furnace, or in subsequent deoxidation, resulting in slag which does not free itself from the metal. Much information has been published concerning these chemical reactions and their control through proper attention to slag viscosity, composition of deoxidizers, and other qualities. The studies of this subject by C. H. Herty, Jr. and others through the medium of physical chemistry have yielded much information for the steel-maker. The second source is erosion of ladle refractories, such as lining brick, stoppers, nozzles and runners, causing entrapped particles of globules of fluxed silicate material. In contrast with the large amount of information available on the first source, relatively little has been published on the subject of erosion which, in the case of basic electric melted steel, is the principal source of nonmetallics. This is probably due to the fact that the problem was assumed to be one of simple mechanical erosion, which could be solved primarily by modification of ladle practices. Good improvements have been made by elimination of slurries in the ladle, better ladle and runner refractories, and more attention to pouring temperatures. It is doubtful, however, that this problem has been recognized in its true light since it is not one of simple mechanical erosion but rather one of chemical reaction between the metal and the refractories; and in this sense is as much a problem of physical chemistry as the reactions involved in the actual steelmaking process.

The influence of ladle refractories on the resulting cleanness of steels was early recognized by A. McCance¹ who examined large inclusions in steels made by both acid and basic practices. His chemical analyses showed the large

influence exerted by the manganese content of the steel on erosion of the ladle and nozzles used in those days. The presence of MnO in such inclusions led McCance to the hypothesis that both basic and acid steels react chemically with the ladle refractories so that small globules of fluxed refractories are carried in the stream into the molds.

This early work of McCance was checked by one of the present authors on basic electric bearing-steel, and it was found that on steels containing as low as 0.40 pct manganese the fluxed surface of the ladle lining after delivering such a heat showed as high as 25 pct MnO by actual analysis. Furthermore, by lowering the manganese content of the steel to 0.20 pct, ladle erosion was decreased with a corresponding decrease in silicate inclusions in the steel. Limitations placed on the manganese content for the required inherent properties made it impossible to pursue this line further, and subsequent attention was concentrated on improved ladle refractories, care in keeping the ladle clean and free from loose refractories up to the time of tapping, and pouring the steel at optimum temperature.

Our study of the chemical reactions at the metal-brick interface between steel and ladle refractories was revived in 1939 as a result of an experimental observation made on the cleanness of alloy steels of the SAE types. This observation showed that the relative cleanness of such steels made in basic

electric arc furnaces of 12 ton capacity and poured in ingots ranging from 1100 to 2200 lb weight was determined to a large extent by the ratio of the manganese and silicon contents, provided other steelmaking variables such as tapping temperature, pouring temperature, pouring time, amount of aluminum added for grain size control, and degree of deoxidation in the furnace were kept reasonably constant. Detailed studies made on the deoxidation and slag practice during the refining period of basic electric furnace practice showed that these two variables exerted some influence on the resulting cleanness of steel in the form of bars and forgings. The important variable, the manganese-silicon balance, was not apparent until heats were made in succession by the best furnace practice kept under fairly rigid metallurgical control.

Another observation pertinent to this work concerned the similarity in the microscope of slag particles causing magnaflux or step-down indications in subsequent rolled bars, and the patches of slag frequently seen on the surface of ingots. These patches are generally believed to come from the glassy metal-brick interface in the ladle and represent an entrapment of such glass (both from the ladle brick and nozzle) in the metal as it flows over the refractories in the neighborhood of the nozzle. These glassy particles are carried down into the mold with the liquid steel, and gradually coalesce into a slag "button" which floats on the surface of the steel as it rises in the molds. Periodically the button is washed to the side of the ingot where it is trapped between the surface of the ingot and the mold, later appearing as a slag patch on the surface of the ingot after stripping.

Even though most of the small glassy particles coalesce into a slag button while the ingot is being poured, it is logical to suspect this step in the steel-making process as being a source of slag lines large enough to cause trouble

on subsequent magnaflux inspection in rolled bars. This is especially true when the furnace practice is known to produce clean steel as shown by samples taken from the furnace just before tapping, and also spooned from the ladle before starting to pour. During the pouring of an ingot, the stream from the nozzle is playing in the center of the mold, and the turbulence created by the stream is such that any particles trapped in the stream will be carried for quite a distance down into the molten metal in the mold, and will then be carried over to sides of the molds before finally reaching the upper surface of the metal. It is to be remembered that the metal is freezing rapidly at the wall of the mold, and that a zone of mushy metal extends inward from the wall. Thus the small slag particles stand a good chance of being trapped in this mushy metal and their chance of doing so should increase as the temperature of the metal is colder or as the rate of pouring the ingot becomes slower.

Now, knowing that a relationship exists between the chemical composition of the steel and the resulting magnaflux inspection of bars and forgings, and further, that a large percentage of the slag particles large enough to cause these magnaflux indications appear to have the same silicate characteristics as the so called "ladle-wash" or metal-brick interface, it seemed reasonable that a detailed study of acid slags formed by the interaction of the ladle brick and the liquid steel would lead to an explanation and correlation of these effects. Before proceeding to examine the actual data resulting from this study, we would like to state the problem of this interaction of ladle refractories and liquid steel in qualitative detail.

In the first place, molten steel will be tapped from a basic electric arc furnace into a ladle lined with brick analyzing 65 pct silica, 30 pct alumina, and 5 pct Fe_2O_3 .* At the metal-brick interface there will form as a result of temperature effects a layer of fused glassy slag which will initially be the composition of the brick. The molten steel, however, contains certain elements and constituents such as man-

FIG 1—Cleanness of SAE 6150 aircraft quality as a function of the final Mn/Si ratio.

ganese, silicon, and ferrous oxide, which will lead to a change in the chemical composition of the fused glass. The composition of the fused glass interface will be modified therefore so that MnO and FeO make their appearance according to the balanced relationships known to exist between slags containing SiO_2 -MnO-FeO- Al_2O_3 and liquid steel containing Fe-Mn-Si-FeO. Thus, depending upon the manganese and silicon contents of the metal and its temperature, the so-called equilibrium slag will be high or low in manganous oxide and high or low in silica, and consequently of high or low fluidity. The appearance of MnO and FeO in the glassy interface as a result of this reaction will cause a decrease in the weight percentage of SiO_2 and Al_2O_3 due to dilution. Depending upon the final composition of this glassy interface, it will slough off easily or with difficulty, as measured by its fluidity or viscosity at the temperature of the interface. Thus the number and composition of the inverse rain of particles trapped in the flow of the metal near the nozzle and carried through the nozzle with the steel, will depend to a large extent upon the chemical composition of the interface and its fluidity or viscosity. The saturation solubility of SiO_2 in slags of this sort is approximately 50 pct by weight and does not vary greatly with temperature. Furthermore, viscosity studies of acid slags containing MnO, FeO, and SiO_2 show that as the acid slag approaches saturation of SiO_2 the viscosity increases greatly.

In view of the above remarks, it appeared worthwhile to review Körber

and Oelsen's² work on equilibrium in the system Fe-Mn-FeO- SiO_2 - Al_2O_3 and to set up a system of calculation so that their results could be extrapolated to cover the equilibrium between molten steel and the glassy interface at the ladle brick. Such a system allows the composition of the equilibrium acid slag to be calculated if the analysis of the metal is known, and this calculated acid slag can be compared with the experimental values obtained for slag "buttons" or slag patches on the side of ingots. If some agreement is obtained by these methods and the experimental data, then it is reasonable to conclude that the occurrence of these slag patches, and also the greater part of the slag-lines in the finished bars, are influenced largely by the interaction of the molten steel with the ladle brick. Conversely, and this is most important, if the composition of the steel can be shown to influence the final cleanliness of the steel, then the problem can be studied with a view to finding general rules for adjusting the composition of the steel to obtain as clean steel as possible.

This report is accordingly divided into three parts. Part 1 will show the step-down data and operating conditions in the furnace, ladle and pit for two grades of SAE steels, SAE 6150* and SAE 3312†. This part will show that if the furnace practice, ladle and pit practices are kept reasonably constant, then there is a relationship between the manganese and silicon ratio in these two grades of steel and the resulting cleanliness. This conclusion will be based both upon the results of our own inspection department and upon magnaflux inspection data of a leading aircraft engine manufacturer. In addition, performance records of a new deep-hardening roller-bearing steel in which the silicon content is adjusted to balance the high manganese content is compared with a similar grade containing high manganese and low silicon contents.

Part 2 will show the chemical analysis of many heats of steel and of the corresponding slag-buttons and slag-patches taken from the sides of ingots. These data will be correlated to show that the manganese-silicon balance of

* Throughout this paper repeated reference will be made to the metal-brick interface in the ladle as the principal example of metal-refractory interaction. However, in the case of ladles using bonded graphite nozzles, the clay bonding material will react in the same manner we ascribe to the ladle brick. Similar remarks will apply to clay or sand mixtures used in the well of the ladle to seal the nozzle in place, and to the bonded graphite heads and sleeves used on the stopper-rod.

the steel determines to a large extent the amount of silica in the slag button or slag patch, and that silica contents of 45 to 50 pct are obtained with manganese to silicon ratios of about unity; and furthermore as the manganese to silicon ratio increases, the amount of silica in the slag button or slag patch decreases, and consequently the viscosity of the slag wash becomes less and will elongate on rolling without shattering.

Part 3 will consider in detail the data of Körber and Oelsen² and J. White³ on equilibrium between silicate slags containing FeO and MnO and molten steel containing Mn, Si, and FeO in solution. The dissociation constants of FeO.SiO₂, MnO.SiO₂, and Al₂O₃.SiO₂ in liquid acid slags will be evaluated through a range of temperatures so that equilibrium can be calculated between acid slags containing SiO₂, FeO, MnO and 25 pct Al₂O₃ and molten steel containing Mn, and Si. The calculated acid slag compositions in equilibrium with steels of various composition will then be compared with the actual slag and metal compositions determined by chemical analyses shown in Part 2.

Part I—Effect of Manganese Silicon Balance on the Cleanness of SAE 6150 and SAE 3312 and a 1.00 pct Carbon Deep-hardening Roller-bearing Steel

The effects of furnace, ladle, and pit practices on the resulting cleanness of steel were studied in considerable detail through a number of years before the manganese-silicon balance was tied down as a source of nonmetallics in the steel. These studies on furnace and pit practice showed that a relatively small effect on cleanness could be definitely tied up with furnace practice. For instance, cleaner steel can be obtained in the SAE grades using slags which deoxidize the metal to a greater degree before metallic deoxidizers (silicon and manganese) are added to the bath. These slags are of low carbide content and are worked on the "wet" side by the use of spar, so that the melter can pour a spoonful of slag and not have to dump it out. High aluminum additions for grain-size control were found to lead to nonmetallic stringers, and the furnace practice was adjusted so that the

minimum of aluminum was added to give grain size test rating of about 7 in SAE 6150. High tapping temperatures were known to give cleaner steel, but there is a limit to the height temperatures can be carried because of obvious effects on furnaces, nozzles, stopper rods, and mold life. Heats of the SAE 6150 type are generally tapped at 1580 to 1600°C, and heats of the SAE 3312 type are tapped at 1600 to 1615°C.

Fast pouring times were found to help the cleanness of the resulting ingot. The heats to be discussed here in detail for the SAE 6150 and 3312 types were cast in 1000-lb ingots measuring approximately 10 in. sq at the top, 8¾ in. sq at the bottom, and about 46 in. high. The pouring time for this size ingot was finally set at 55 to 60 sec from start of pouring the ingot to the shut-off at the bottom of the hot-top.

Table 1 shows a typical log of one of these heats of SAE 6150, showing complete steel and slag analyses throughout the melting process.

After several heats of SAE 6150 were made according to the furnace, ladle, and pit practice summarized in Table 1, the effect of the manganese-silicon

ratio upon cleanness became apparent on steel rated by step-down tests rolled from pilot bars. The pilot bars represented two tops, one middle, and two bottom billets from each heat. The billet stock in all cases was disc inspected before pieces were cut for rolling to 1½ in. rd. bars. Step-down tests representing steps of ⅛ in. off the diam, and ¼ in. off the diam were turned on these rolled bars. The length of each step was approximately 4 to 5 in. in all cases.

In order to rate numerically a heat of steel in terms of its step-down inspection it is convenient to give some numerical weight to the different classes of slag-lines. The routine practice on inspection is to designate the length of slag lines by five classes, and to assign a numerical weight to each of the various classes to penalize the longer slag lines. This system is as follows.

| Class | Length of Lines | Numerical Weight |
|-------|--------------------|------------------|
| 1 | Up to ⅛ in. | 1 |
| 2 | ⅛ to ¼ in. | 2 |
| 3 | ¼ to ⅜ in. | 4 |
| 4 | ⅜ to ½ in. | 8 |
| 5 | Greater than ½ in. | 16 |

This classification for frequency and length of slag lines is extended a step further to penalize slag lines which occur in the tops and middles as compared to the bottoms. The first step in using this system of numerically rating a heat for cleanness is to obtain the sum of the number of lines in each class multiplied by their weight factor, and then to further multiply the top and middle sums by 2. The total summation is then divided by the number of steps inspected to obtain the numerical rating of the heat.

This system is illustrated by the following example:

Pilot Bar Inspection . . . 5 in
Length 1½ rd. Bars

| Middles... | 7 | 6 |
| Bottoms... | 7 | 5 |

Rating of heat on basis of a weight of 2 for tops and middles equals 20.

The cleanness ratings of successive heats of SAE 6150 made for the aircraft engine industry in 1939 and inspected on the basis of counting visually the slag lines and rating them according to length are shown in Table 2. Fig 1 shows these step-down ratings of the heats as a function of the manganese-silicon ratio for the heats. Here it is seen that as the manganese-silicon ratio decreases the step-down rating becomes less, that is, the heats become progressively cleaner on the step-down inspection.

The dates of melting and inspection of these early heats of SAE 6150 were about 1939 and 1940, and this practice of working to as high a silicon content as possible was adhered to throughout the war. The manganese was kept on the low side of the chemical limit for this specification, and several heats were inadvertently made using a silicon content of 0.60 pct and a manganese content of 0.70 pct. These heats ran true to form, and were cleaner on step-down inspection in $1\frac{1}{2}$ -in. rolled bars.

Recently we have had another confirmation of the effect of the manganese-silicon ratio on the cleanness of rigidly inspected steels made to AMS 6260* which is a modification of SAE 3312. For many years before the war our custom was to melt a proprietary alloy grade similar to SAE 3312 steel to manganese limits of 0.30 to 0.50 pct and silicon limits of 0.25 to 0.40 pct. The SAE limits for 3312 allowed the manganese to be made substantially equal to the silicon content so that the manganese-silicon ratio was approximately unity. When the AMS specifications were set up however, we worked to the upper part of the manganese limits of 0.40 to 0.70 pct because of hardenability requirements and the silicon limits of 0.20 to 0.35 pct, so that a manganese-silicon ratio of at least 1.7 was inevitable, and generally this ratio on actual heats of steel was at least 2.00. From the beginning of manufacture of AMS 6260 it was noticed that the heats were considerably dirtier than our proprietary grade of alloy

* AMS 6260: C 0.07/0.13 pct, Mn 0.40/0.70 pct, Si 0.20/0.35 pct, P 0.040 pct max., Cr 1.00/1.40 pct, Ni 3.00/3.50 pct, Mo 0.08/0.15 pct.

similar to SAE 3312 in which the silicon was made about equal to the manganese content.

A cooperative program was arranged with an aircraft engine manufacturer to make two heats of AMS 6260 to limits 0.30 to 0.60 pct for both the manganese and silicon. The performance of these two heats was compared with the performance of previous heats of AMS 6260 made to the high manganese and low silicon limits. All of these heats were of our own manufacture so that complete records were available both in our own inspection department and from the aircraft engine manufacturer's magnaflux reports.

Table 3 shows a typical melting log of AMS 6260, the practice shown being a carryover from the practice used in making SAE 3312 to high standards for cleanliness. Tapping temperatures were held to the range 1600/1615°C, and 1000-lb ingots were poured in 55 to 60 sec.

Table 4 shows the Carpenter inspection data on step-down tests on pilot bars where available, and miscellaneous step-down reports taken from random bars on production orders, and also the percentage rejection on magnaflux inspection of knuckle pins in an aircraft engine manufacturer's plant. The same method of rating the heats on step-down tests was used as that described

above, except that in the case of production lots no weight could be given top and middle as in the pilot bar inspection. (Here it is to be remarked that previously SAE 3312 was supplied for this part for some length of time, and the losses were consistently in the neighborhood of 5 pct or less on final rejection of this difficult knuckle pin and piston pin inspection. On these heats the manganese was held to about

FIG 2—Relationship between Mn/Si ratio heats of AMS 6260 and per cent reduction of aircraft knuckle pins, magnaflux inspection.

0.40 pct and the silicon content was in the neighborhood of 0.35 pct.)

Table 4 shows clearly the relation of manganese to silicon ratio on five heats, to both step-down inspection data in our own plant and magnaflux inspection of finished aircraft parts. Fig 2, plotted from some of the data in Table 4, shows the relationship between the manganese to silicon ratio and the percentage rejection of knuckle pins on magnaflux inspection. Here again the conclusion is obvious that the manganese and silicon contents of the heat of steel can exert a large influence on the resulting cleanliness of the steel when other operating variables are controlled closely.

An additional example can be quoted

FIG 3—Effect of Mn/Si ratio on the Si content of slag buttons from surfaces of ingots.

to show that the manganese to silicon balance has a large effect on the resulting cleanness of steel when made in the basic electric arc furnace and teemed into ingots from a ladle lined with acid brick. This example has to do with a steel analyzing approximately 1.00 pct C, 1.50 pct Si, 1.50 pct Mn, and 2.50 pct Cr. This steel was developed for the manufacture of large rollers and races which must pass magnaflux testing. The steel previously used analyzed approximately 1.00 pct C, 0.60 pct Si, 1.75 pct Mn and 1.50 pct Cr. When using the latter oil hardening steel the results of hair-line inspection on rollers were very erratic. Some heats were good, but when hair lines occurred they were bad and resulted in rejections of 15 to 50 pct. With the steel containing

Table 4 . . . Stepdown and Magnaflux Inspection Data on AMS 6260, Aircraft Quality

| Heat | Mn/Si Ratio | Weighted Average per 6 In. Length | | Pct Rejection on Knuckle-Pin Inspection |
|------|-------------|-----------------------------------|------------|---|
| | | Production Orders | Pilot Bars | |
| A | 1.62 | 15.6 | | 24 |
| B | 2.48 | 21.6 | | 38 |
| C | 2.12 | 24.0 | | 35 |
| D | 0.69 | 7.0 | 14.4 | 3.9 |
| E | 0.83 | 8.4 | 5.3 | 3.0 |

1.00 pct C, 1.50 pct Si, 1.50 pct Mn and 2.50 pct Cr, the rejections are uniformly less than 2 pct.

Having established the effect of the manganese-silicon balance on the cleanness of steels when made by carefully

controlled melting and pit practice, the problem was now to find a logical explanation for this effect.

Part 2—The Effect of the Manganese Silicon Ratio on the Silica Content of Slag Patches on Ingot Surfaces

In the introductory remarks we pointed out the possible effect of manganese and silicon contents of molten steel on the chemical composition of ladle wash, as evidenced by the slag patches commonly found on the surface of the metal as it is rising in the molds. It was suggested that the principal effect of the manganese and silicon content of the steel on the ladle brick and metal interface would be to form a slag whose viscosity, or fluidity, would be determined by this balance of manganese and silicon.

Slag buttons were collected from the surface of ingots, and in some cases from the upper surface of the steel as it was poured in the molds. This investigation was not concerned with any particular grade of steel because the general chemical composition of such slag buttons was desired. Consequently a variety of SAE grades of steel were sampled, in addition to several grades of tool steels.

Table 5 shows analysis of the metal and of the corresponding slag buttons collected from these heats. For the purpose of this discussion it is sufficient to show the total silica, total alumina,

total iron as FeO, MnO and Cr₂O₃ composition of these slags.

These slag analyses fall into two groups, first, those having up to about 25 pct Al₂O₃ and second, a few showing approximately 35 pct Al₂O₃. Fig 3 shows the total silica content of these slag buttons as a function of the manganese-silicon ratio of the steel from which they were collected. Two groupings are shown in Fig 3 corresponding to the two Al₂O₃ contents of the slag buttons. Considering first the 25 pct Al₂O₃ group, it is seen that the saturation value for this type of slag approaches 45 to 50 pct by weight, and that the saturation value is rapidly approached as the manganese-silicon ratio approaches unity. At a manganese-silicon balance of 1.5 the silica concentration of these slags drops to 40 pct, and at a ratio of 2.50 the concentration drops steadily to 35 pct. After this the silica concentration drops gradually with increasing manganese to silicon ratios, until in the region of manganese contents of 1.25 to 1.75 pct, with silicon values of about 0.25 pct, the silica concentration is about 30 pct.

The same general conclusions are obtained on the few samples containing approximately 35 pct Al₂O₃. Here the saturation silica concentration seems to be approximately 40 pct, and this saturation value for silica is reached at a manganese-silicon ratio of somewhat less than unity. At a manganese-silicon ratio of unity the silica concentration in the slag buttons is approximately 35 pct, while at a manganese-silicon

*TS = Tool Steel.

ratio of 3 the silica concentration is approximately 30 pct by weight.

Fig 3 confirms the results of Körber and Oelsen² on the saturation solubility of silica in acid slags containing about 25 pct alumina, and other quantities of FeO and MnO. Due to the nature of the sampling in our experiments on these slag buttons, some spread in values is to be expected for the total silica content, but the data do indicate that a saturation value of 45 to 50 pct by weight silica is found in these acid slags containing about 25 pct alumina.

From the behavior of the slags containing approximately 35 pct alumina, it is clear that the saturation solubility of silica is evidently lower in these slags than in the 25 pct alumina series. Only 5 heats were found which showed 35 pct alumina in their slag buttons, and the reason for these heats deviating from the 25 pct alumina type is not known.

For the time being it is well to remember that Herty, Conley and Roger⁴ measured the viscosities of slags in the acid slag system FeO-MnO-SiO₂ at about 1550°C. They found that as the silica concentration of the slag approached saturation at this temperature, then the viscosity of the slag increased greatly. Körber and Oelsen² found the saturation solubility of silica in slags composed of FeO, MnO, and SiO₂ to be approximately 50 pct by weight at 1600, 1550 and 1500°C. Körber and Oelsen² also found the saturation solubility of silica to be 50 pct in slags composed of 25 pct alumina, ferrous oxide and manganous oxide.

Part 3—Calculation of Equilibrium between Liquid Metal and Acid Ladle Brick

The foregoing data relating to the effect of the manganese silicon balance on the resulting cleanness of basic electric arc melted steels, and on the silica content of slag buttons and slag patches on the sides of ingots, have been interpreted qualitatively on the basis that the manganese and silicon contents of the steels have a large effect on the chemical composition of the interface between the molten metal and the ladle brick. As the manganese-silicon ratio in steel becomes unity or less, the steels become cleaner on any test which measures the macroscopic cleanness of the steel, such as the magnaflux or step-down methods. Furthermore, we have shown that as the manganese-

silicon ratio becomes unity or less, then the composition of the slag buttons on the sides of ingots becomes such that the silica content is rapidly approaching saturation. From experimental studies on acid slags, we know that the viscosity of such slags increases rapidly as the silica content approaches saturation.

There is another method of attack which can be used to test the hypothesis that the genesis of these slag buttons, and hence the slag lines, is at the metal-brick interface in the ladle, and that is to set up a system to calculate the composition of these slag buttons from the chemical composition of the heat. Such a method can make use of the available laboratory studies which have been made on the equilibrium of molten steel under acid slags. Admittedly the molten steel-brick inter-

Table 6 . . . Silicon-FeO Balanced Reaction in Liquid Steel

| Temperature, °C | [Si] × [FeO] ² |
|-----------------|---------------------------|
| 1600 | 7 × 10 ⁻⁴ |
| 1550 | 2.72 × 10 ⁻⁴ |
| 1500 | 0.78 × 10 ⁻⁴ |

Table 7 . . . Distribution of Free Ferrous Oxide between Slag and Liquid Iron

| Temperature, °C | Mol Per Cent FeO in Slag Pct by Wt. FeO in Metal |
|-----------------|---|
| 1550 | 85 |
| 1575 | 77 |
| 1600 | 69 |

face is not at equilibrium in a strict sense of the word, since the interface is continually breaking up into small globules, and a new interface is being formed by reaction of the steel with the brick which contains approximately 65 pct silica, 30 pct alumina, and 5 pct ferric oxide. However, at the temperatures of molten steel in the ladle there is a good chance that the reaction rates are fast enough so that the composition of the interface approximates the equilibrium composition.

The experiments of Körber and Oelsen² on the equilibrium of molten steel containing manganese and silicon under acid slags containing FeO, MnO and silica, when the slag is saturated with silica, can be used to calculate* the dissociation constants of ferrous and manganous silicates in acid slags. To do this, it is necessary that a value be known for the solubility product of [Si] × [FeO]². The value determined by Körber and Oelsen's² data probably

* The calculations which follow are similar to those made by H. Schenck, *Physikalische Chemie der Eisenhüttenprozesse*, 2, J. Springer, Berlin,

represents the best value available at the present time. Their values for this product, expressed in terms of per cent by weight silicon and FeO in solution in liquid steel are given in Table 6.

The distribution ratio of Herty and Gaines⁵ showing the free mol pct of FeO in liquid slags divided by the pct by weight of FeO in liquid steel may be expressed as in Table 7.

The relationships of Tables 6 and 7 may be combined to give the product of (Si) × (Free mol pct FeO in the slag)² as shown in Table 8.

The experiments of Körber and Oelsen² used liquid steel in sand crucibles in which melts of iron, manganese and silicon were allowed to come to equilibrium with acid slags containing FeO, MnO and silica. Since the crucibles were of sand, the slags were saturated with silica. Considering the constitution of the slag phase, we would like to emphasize that the following remarks on the probable molecular constitution of these slags are made in the light of setting up a set of molecular dissociation constants which may or may not have the correct physical meaning. What we plan to do is to obtain a set of molecular dissociation constants for these acid slags which will reproduce Körber and Oelsen's² data, and then these constants will be used to calculate the probable equilibrium between acid slags and liquid steel under conditions different from those of the laboratory experiments.

Table 8 . . . Balanced Reaction between Pct Si in the Metal and Free Mol-pct FeO in Slags, and by Pct Weight FeO in Slag if the Number of Mol per 100 G, M, is Known

| Temperature, °C | [Si] × (FeO) ² | [Si] × {FeO} ² |
|-----------------|---------------------------|---------------------------|
| 1550 | 1.98 | 1.06 M ² |
| 1575 | 2.72 | 1.43 M ² |
| 1600 | 3.32 | 1.73 M ² |

The constitution of the slags will be FeO, MnO and SiO₂, and the molecular constituents present will be taken to be free FeO, free MnO, free SiO₂, and FeO.SiO₂ and MnO.SiO₂. The ordinary chemical analysis will yield only the

1934. However, different values for the dissociation constants of FeO.SiO₂ and MnO.SiO₂ are used by Schenck in his work than those which we will presently derive. For this reason, we will show briefly our method of calculating and checking those dissociation constants.

total amounts of FeO, MnO and SiO₂. The amount of free FeO, as distinct from the amount of FeO combined with silica can be obtained by use of the silicon-ferrous oxide solubility product. If the silicon content is known, then Table 8 will give the amount of ferrous oxide present in solution, but uncombined with silica, in the slag. Assuming that the mol percent of free FeO can be converted to percent by weight of FeO (this can be done if the molecular weight of the slag is known), then a subtraction of this value from the total per cent by weight of FeO present will yield the amount of FeO combined with silica.

The equilibrium between manganese in liquid steel and free FeO and free MnO in slags is known from the experiments of Krings and Schackmann⁶ and Körber and Oelsen.² This relationship is of the form:

$$K_{Mn} = \frac{\{MnO\}}{\{FeO\}[Mn]} \tag{1}$$

and values for K_{Mn} are shown in Table 9. In Table 9 the FeO and MnO quantities refer to weight percent of uncombined FeO and MnO in the slags.

Table 9 . . . Balanced Reaction between Free FeO and MnO in Slags and Mn by Weight in Liquid Steel

| Temperature, °C | $K_{Mn} = \frac{\{MnO\}}{\{FeO\}[Mn]}$ |
|-----------------|--|
| 1575 | 2.2 |
| 1600 | 2.0 |
| 1625 | 1.8 |

Thus, knowing the manganese content of the liquid metal and the free FeO as determined from the silicon content as outlined above, the free MnO content of the slag can be calculated. A subtraction from the total MnO content as determined by chemical analysis will determine the amount of MnO combined with silica.

J. White³ has published experimental data on the dissociation of FeO.SiO₂ in liquid acid slags at temperatures ranging from 1550 to 1625°C. White's data can be represented by the following relationship:

$$\text{Log} \frac{(\text{FeO}.\text{SiO}_2)}{(\text{FeO})(\text{SiO}_2)} = \frac{7170}{T} - 5.211 \tag{2}$$

where the concentrations are in mol percents, and T is the absolute temperature.

When the dissociation constant for FeO.SiO₂ is determined from Körber

FIG 4—FeO-MnO-SiO₂ slags, 1600°C.

and Oelsen's² data as outlined above, it is found that the value is virtually in agreement with White's value in Eq 2. This indicates that White's dissociation constant is consistent with the data of Körber and Oelsen.² The dissociation constant for MnO.SiO₂ determined from Körber and Oelsen's² data as outlined above is

$$\text{Log} \frac{(\text{MnO}.\text{SiO}_2)}{(\text{MnO})(\text{SiO}_2)} = \frac{6030}{T} - 3.52 \tag{3}$$

where the concentrations are in mol percents, and T indicates the absolute temperature.

Equilibrium at 1600°C in the system Fe-Mn-Si-FeO-MnO-SiO₂ may be computed by means of these two dissociation constants, and Tables 6, 7, and 8. These calculations are summarized in Fig 4, where the MnO and FeO contents of an acid slag are shown as a function of the Mn and Si contents of the bath. The shaded line in Fig 4 indicates the saturation value of 50 pct for silica as found by Körber and Oelsen.² The balanced manganese and silicon content under an acid slag containing 50 pct silica may be determined by reading the intersection of the Mn and Si lines with this 50 pct silica line. Thus, for 0.30 pct Mn, the corresponding silicon content for 50 pct SiO₂ is 0.09 pct; for 0.50 pct Mn the silicon is 0.15 pct; and for 0.70 pct Mn the silicon is about 0.28 pct. Fig 5, curve A shows the experimental Mn and Si contents in liquid steel at 1600°C under acid slags containing 50 pct silica, after Körber and Oelsen.² The calculated values determined from Fig 4 are

shown as squares, and the conclusion is drawn that these dissociation constants for MnO.SiO₂ and FeO.SiO₂ reproduce Körber and Oelsen's² data over a considerable range of Mn and Si contents.

Körber and Oelsen² also determined the Mn and Si contents of liquid steel under acid slags containing 25 pct Al₂O₃ and 50 pct SiO₂ at 1600°C. These data are reproduced in Fig 5, curve B. The dissociation constant for Al₂O₃·SiO₂ = 0.49 (this is the same value as the dissociation constant for MnO.SiO₂ at this temperature) yields the curve shown in Fig 5, labeled curve C. Larger dissociation constants for Al₂O₃·SiO₂ do not make significant changes in this curve, therefore this is as far as this type of analysis can be carried at the present time to determine the dissociation constant for Al₂O₃·SiO₂.

The temperature variation of the dissociation constant for Al₂O₃·SiO₂ is taken to be the same as MnO.SiO₂.

The equations used at temperatures of 1550 and 1500°C to calculate the composition of acid slags containing about 25 pct alumina as a function of the manganese and silicon content of liquid steel are shown below:

25 pct Al₂O₃-FeO-MnO-SiO₂-Slags at 1550°C*

$$\Sigma \text{FeO} = \{ \text{FeO} \} \left[1 + \frac{0.086}{M} \{ \text{SiO}_2 \} \right]$$

* In Eq 4, 5 and 6, [] refers to weight percentage in liquid steel, Σ indicates the total percent by weight of SiO₂, or MnO, etc. in the slag phase, { } indicates the percent by weight of a molecular constituent, such as free SiO₂, free MnO, etc. in the slag phase, and M is the number of mols per 100g when the slag constituents are computed as free FeO, FeO.SiO₂, free MnO, etc.

FIG 5—Mn-Si balance at 1600°C in liquid steel under acid slags saturated with silica ($\Sigma\text{SiO}_2 = 50$ pct).

$$\Sigma\text{MnO} = \{\text{MnO}\} \left[1 + \frac{1.00}{M} \{\text{SiO}_2\} \right]$$

$$\Sigma\text{SiO}_2 = \{\text{SiO}_2\} \left[1 + \frac{0.072}{M} \{\text{FeO}\} + \frac{0.84}{M} \{\text{MnO}\} + \frac{0.60}{M} \{\text{Al}_2\text{O}_3\} \right]$$

$$\Sigma\text{Al}_2\text{O}_3 = \{\text{Al}_2\text{O}_3\} \left[1 + \frac{0.97}{M} \{\text{SiO}_2\} \right] = 25 \text{ pct}$$

$$[\text{Si}]\{\text{FeO}\}^2 = 1.06M^2$$

$$[\text{Mn}] = 0.418 \frac{\{\text{MnO}\}}{\{\text{FeO}\}} \quad [4]$$

25 pct Al_2O_3 -FeO-MnO-SiO₂ Slags at 1500°C*

$$\Sigma\text{FeO} = \{\text{FeO}\} \left[1 + \frac{0.11}{M} \{\text{SiO}_2\} \right]$$

$$\Sigma\text{MnO} = \{\text{MnO}\} \left[1 + \frac{1.26}{M} \{\text{SiO}_2\} \right]$$

$$\Sigma\text{SiO}_2 = \{\text{SiO}_2\} \left[1 + \frac{0.11}{M} \{\text{FeO}\} + \frac{1.06}{M} \{\text{MnO}\} + \frac{0.76}{M} \{\text{Al}_2\text{O}_3\} \right]$$

$$\Sigma\text{Al}_2\text{O}_3 = \{\text{Al}_2\text{O}_3\} \left[1 + \frac{1.22}{M} \{\text{SiO}_2\} \right] = 25 \text{ pct}$$

$$[\text{Si}]\{\text{FeO}\}^2 = 0.86M^2$$

$$[\text{Mn}] = 0.32 \frac{\{\text{MnO}\}}{\{\text{FeO}\}} \quad [5]$$

Further, the calculated free, or uncombined, alumina in these slags will be about 2.5 pct by weight when calcu-

lated according to the above sets of formulas, and the mols per 100 g in the slag will be about 0.93 (M). The free silica can be obtained approximately by

$$\{\text{SiO}_2\} = \frac{75 - \{\text{FeO}\} - \{\text{MnO}\}}{1 + \frac{0.158}{M} \{\text{FeO}\} + \frac{1.84}{M} \{\text{MnO}\} + \frac{1.5}{M}} \quad [6]$$

As a sample calculation, let the manganese content of liquid steel in the ladle be 0.70 pct and the silicon content 0.17 pct, and we desire to calculate the total FeO, MnO and SiO₂ contents of the equilibrium slag containing 25 pct Al_2O_3 . Take the temperature as 1550°C. Let $M = 0.93$, then

$$\{\text{FeO}\} = \sqrt{\frac{0.91}{0.17}} = 2.32$$

$$\{\text{MnO}\} = \frac{0.70 \times 2.32}{0.418} = 3.88$$

$$\{\text{SiO}_2\} = \frac{75 - 6.20}{1 + 0.39 + 7.70 + 2.06} = \frac{68.80}{11.15} = 6.2$$

$$\{\text{Al}_2\text{O}_3\} = \frac{25}{1 + 6.48} = 3.34$$

$$\Sigma\text{FeO} = \text{Total FeO} = 2.32$$

$$[1 + 0.572] = 3.64$$

$$\Sigma\text{MnO} = \text{Total MnO} = 3.88$$

$$[1 + 6.68] = 29.80$$

In terms of mol per 100 g, these are $\text{FeO} = 0.0505$, $\text{MnO} = 0.4380$, $\text{Al}_2\text{O}_3 = 0.3470$, and free $\text{SiO}_2 = 0.103$, to give $M = 0.938$. These calculated total FeO and MnO contents of the slag are to be compared with $\text{FeO} = 5.4$ and $\text{MnO} = 32.9$ found experimentally for heat (10) shown in Table 5.

In a similar manner, a broad range of FeO and MnO contents of acid slags containing 25 pct Al_2O_3 and the remainder silica can be calculated as a function of the manganese and silicon content of the liquid steel. These calculations are summarized in Fig 6 and 7 for temperatures of 1550 and 1500°C.

Table 10 shows the predicted MnO and FeO contents in the equilibrium acid slag containing 25 pct Al_2O_3 , balance silica slags for the manganese and silicon contents of the heats shown in Table 5. In general the trend is evident that Fig 6 and 7 predict with reasonable accuracy the composition of the slag buttons found on ingots. Considering the fact that equilibrium is

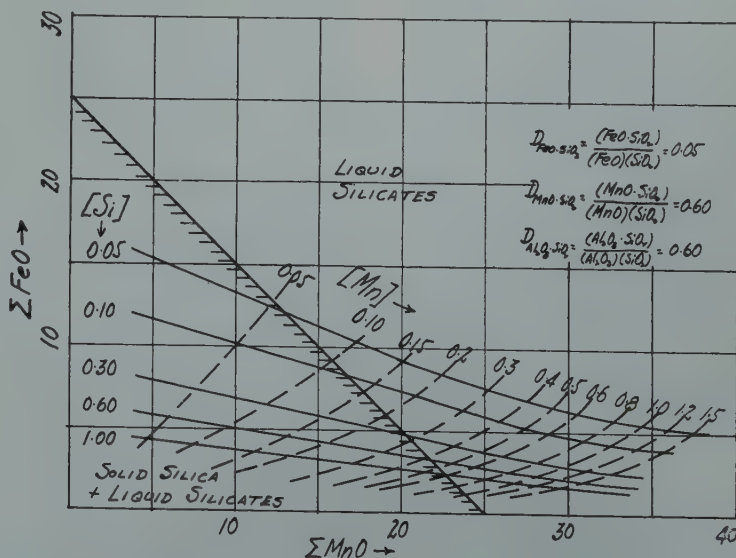

FIG 6—25 pct Al_2O_3 -FeO-MnO-SiO₂ slags 1550°C.

* See footnote on p. 23.

manganese and silicon contents of the liquid steel in the ladle determine to a large measure the chemical nature of the interface between ladle brick and metal.

Summary and Conclusions

1. Data have been presented to show the effect of manganese and silicon contents of basic electric arc melted steel on the resulting cleanliness as measured by the magnaflux test or step down-rating for heats representative of SAE 6150, AMS 6260 and a 1 pct carbon, high manganese, high silicon roller bearing grade of steel. These data show that a high manganese content together with a low silicon content of the steel leads to more nonmetallic indications on step-down tests than are present when the manganese and silicon contents are substantially equal. This effect is quite clear on the three grades discussed here, and the effect was apparent when heats were made in succession by fairly rigid control procedures governing the deoxidation practice, refining slag practice, tapping temperatures and pouring times, and using the minimum of aluminum for grain size control. The data apply particularly to basic electric steels melted in 12-ton furnaces and ingot sizes of 10 to 15 in. square (1000 to 2000 lb ingot weight).

2. Experimental data have also been shown which indicate that the manga-

probably not reached in the glassy brick-metal interface but is approached to some degree before the glassy globules slough off and either rise to the surface of metal in the ladle or are trapped in the stream near the nozzle and carried into the ingot, the calculations are as good as can be expected.

The degree with which the composition of the slag buttons on the surface of ingots melted in the basic electric arc furnace can be calculated, leads to the conclusion that this slag is coming from the ladle and represents globules of the glassy interface between ladle brick and the liquid metal. These compositions were computed on the basis of equilibrium data obtained by allowing liquid steel to come to equilibrium with acid slags in silica crucibles. Thus, the reasonable agreement found between these calculated slags and the composition of the slag button shows that the

FIG 7—25 pct Al₂O₃-FeO-MnO-SiO₂ slags 1500°C.

nese and silicon contents of the liquid steel, as expressed by the manganese to silicon ratio, do in fact affect markedly the silica content of slag buttons collected from the sides of ingots. Qualitative microscopic data indicate that a large percentage of nonmetallics which cause magnaflux and step-down rejections have the same characteristics as these slag buttons and ladle wash.

3. Detailed calculations are summarized to show that an extension of equilibrium data obtained by Körber and Oelsen² in iron melts containing manganese and silicon under $\text{SiO}_2\text{-FeO-MnO-Al}_2\text{O}_3$ slags accounts reasonably well for the observed slag patch analyses obtained experimentally.

4. A detailed picture of the chemical influence of liquid steel on the physical characteristics of the metal-brick interface is presented in view of the above experimental data. We adopt the outlook that the majority of nonmetallics which are detected by means of macroscopic tests such as the magnaflux test or step-down ratings have their genesis at the interface between liquid steel and ladle brick, and the nozzle. When liquid steel is tapped from a basic electric arc furnace into a ladle lined with brick containing about 65 pct SiO_2 -30 pct Al_2O_3 -5 pct Fe_2O_3 , the brick is first softened or melted at the metal-brick interface. Chemical reactions then take place between the liquid steel and this interface so that its chemical composition approaches that of an equilibrium acid slag containing $\text{SiO}_2\text{-MnO-FeO}$ and Al_2O_3 . The chemical composition of this slag will have a marked influence on its viscosity and hence its ability to resist erosion. For silica contents near the saturation value for such slags, that is about 50 pct SiO_2 , coupled with low

MnO values, the slag will show a somewhat higher viscosity than would result if the silica content were lower than its saturation value. The data we have shown above in fact represent a study of the influence of the manganese and silicon content of liquid steel on the resulting silica content of this metal-brick interface, as reported by the slag buttons and slag patches from the sides of ingots.

As the steel flows through the nozzle of the ladle the inverse rain of acid slag globules coming from the metal-brick interface in the neighborhood of the nozzle are trapped in the steel and carried down into the ingot mold as the metal is being teemed. These nonmetallics are carried for a considerable distance below the surface of the metal as it rises in the molds, and are swept to the sides and upward as a result of the velocity gradients created in the liquid steel by the force of the stream. The metal is freezing from the sides of the mold inward, and a mushy zone of metal extends for a considerable distance into the body of the liquid steel because of the high rate of heat conduction at the mold wall. Thus these nonmetallics stand a good chance of being trapped in this zone of mushy metal as the ingot is being teemed. Cold metal and slow teeming together or separately will lead to more entrapment of these nonmetallic globules, other conditions remaining constant.

Thus, starting with attention focused on tapping temperatures, pouring times and several operating variables in the furnace, the electric furnace operator can take a large step in cleaning up nonmetallics in such steels by focusing attention on the manganese and silicon balance of the steel. The effect is considerable and can be accomplished easily provided chemical specifications will permit.

5. In view of the above effect of manganese and silicon on the cleanness of basic electric arc melted steel, and the importance of such cleanness in aircraft and specialized alloy steel uses, it is suggested that the engineering societies concerned with steel specifications review the silicon contents of these specifications. Such reviews should be directed toward enabling the steelmaker to balance the silicon content against the manganese content where possible, to take advantage of the effect of these two elements on the resulting cleanness of steel.

Acknowledgment

The authors gratefully acknowledge the cooperation of Mr. C. C. Wilson, Superintendent of Melting, the active assistance of Mr. D. G. Schoffstall in the chemical phases of this work, and the encouragement of Mr. J. H. Parker, Chairman of the Board, and Mr. B. H. DeLong, Vice President, The Carpenter Steel Co., without which this work would not have been possible.

The Influence of Temperature on the Affinity of Sulphur for Copper, Manganese, and Iron

E. M. COX,* M. C. BACHELDER,* N. H. NACHTRIEB* and A. S. SKAPSKI*

As a result of using copper-containing scrap in the steelmaking process, the copper content of steels has been steadily increasing for years. Consequently the possible role copper may play in the steelmaking process and in the finished product begins to attract the metallurgists' attention. Some time ago one of the present authors forwarded the idea—based on the results of the analysis of nonmetallic inclusions extracted electrolytically from steels—that sulphur in plain carbon steels is distributed mainly between copper and manganese, the amount of iron sulphide being very small; and that, consequently, the problem of copper and that of sulphur in steel cannot be treated separately.¹

At the time of the publication of the quoted paper little was known about the relative affinities of copper and manganese for sulphur at high temperatures except that at moderate temperatures (below 1000°C) the affinity of manganese for sulphur is much greater. To gather more experimental data on this subject, the present authors undertook the investigation of the equilibrium constants of the reactions:

over a range of temperatures wide enough to establish the dependence of these equilibrium constants on temperature. From the equilibrium constants ($K = 1/P_{\text{S}_2}$) the free energy of formation (affinity) can be calculated

from

$$\Delta F^\circ = -RT \ln 1/P_{\text{S}_2} \quad [1]$$

where the standard conditions chosen are: 1 atm of sulphur pressure and the activities of condensed components equal one.

The decomposition pressure, P_{S_2} , of sulphur over the respective sulphides is too small to be measured directly, but there is a way of eliminating this difficulty by measuring the equilibrium constant of the reaction between the sulphide and hydrogen. From the latter and from the equilibrium constant of the thermal dissociation of H_2S we then calculate P_{S_2} for the respective sulphide.

The numerical values of the equilibrium constant of the thermal dissociation of H_2S at different temperatures were taken from Kelley's paper, "The Thermodynamic Properties of Sulfur and its Inorganic Compounds."²

In previous experimental work published by Jellinek and Zakowski³ and by Britzke and Kapustinsky⁴ the equilibrium constants of the reactions *Metal sulphide* + $\text{H}_2 = \text{H}_2\text{S}$ + *metal* were determined by passing hydrogen, at different rates of flow, over the sulphide, analyzing the resulting H_2S + H_2 mixture and then extrapolating the $\text{H}_2\text{S}/\text{H}_2$ ratio (which is a function of the rate of flow) to the zero speed of

flow, a method necessarily involving considerable uncertainty. In the present work the equilibrium ratio was actually measured instead of being extrapolated. The apparatus is shown in Fig 1.

Experimental Procedure

The sulphides were prepared by the following methods:

FeS

Powdered iron which had been reduced with hydrogen (ferrum reductum) was mixed in stoichiometric ratio with sublimed sulphur and carefully ground. The mixture was put into an alundum crucible, covered with pure sulphur, and the reaction started by touching the mixture with a glowing iron rod. After the reaction was completed the product (still containing some metallic iron) was again ground with sulphur, put into a Rose crucible, covered with sulphur, and heated in a strong current of pure hydrogen. Analysis of the final product showed 62.46 pct Fe and 36.59 pct S. Theoretical for FeS: 63.53 pct Fe and 36.47 pct S.

MnS

Manganese sulphide (precipitated and carefully washed with distilled water containing H_2S) was dried in a Rose crucible in an atmosphere of H_2S and heated in a current of hydrogen for 2 hr at red heat. The product was then ground and ignited for several hours at 1000°C in a current of hydrogen sulphide. Analysis showed 64.53 pct Mn and 36.63 pct S. Theoretical: 63.15 pct Mn and 36.85 pct S.

Some MnS samples were prepared from metallic manganese and sublimed sulphur by mixing and grinding them and then heating in a current of hydrogen sulphide in an alundum tube.

* Regardless of the form in which copper sulphide may be found in steel at low temperatures (be it Cu_2S or CuS), the high temperature reactions are concerned only with Cu_2S , CuS being unstable above the temperature of red heat.

FIG 1—Diagram of apparatus.

No difference was noticed between the MnS samples obtained by the two methods, as far as the value of the equilibrium constants was concerned.

Cu₂S

Reagent grade CuCl₂ was dissolved in hydrochloric acid solution and treated with hydrogen sulphide. The precipitate of cupric sulphide was washed with glacial acetic acid and dried at 110°C. It was then placed in a Rose crucible and heated in a stream of hydrogen at 600°C for 30 min. Analysis showed 79.78 pct Cu and 19.68 pct S. Theoretical for Cu₂S: 79.86 pct Cu and 20.14 pct S.

The alundum boat A containing a few grams of powdered sulphide (or a mixture of sulphide and the respective metal) was placed in a vacuum-tight tube (quartz, mullite, or Norton Co. RA1164 alundum) about 36 in. long and about 1 in. id, which was mounted inside the furnace B; the region of uniform temperature inside the tube was found to exceed the length of the boat by a few inches on each side. The rest of the system was of pyrex glass and was connected to the ends of the furnace tube by means of Apiezon, in the case of the alundum tube. When the quartz furnace tube was employed the connections were by means of graded quartz-to-pyrex seals. When the mullite tube was used, uranium glass was the intermediate in the mullite-to-pyrex seal. The Apiezon connections used for the alundum tube were always kept cool,

if necessary by blowing a current of air on them. After the system had been evacuated and checked for tightness, carefully purified hydrogen (tank hydrogen passed through 1:1 KOH, concentrated KMnO₄, Pd-asbestos at 500°C, and P₂O₅) was admitted up to atmospheric pressure and the system evacuated again, the operation being repeated three times to insure the removal of any traces of oxygen which might have remained in the system after evacuation. The temperature was then set at the desired level and kept constant by means of a Micromax controller. The thermocouple connected with the Micromax was placed *outside* of the reaction tube while the thermocouple measuring the temperature of the reaction was placed *inside* the tube directly over the boat containing the sample. This arrangement assured a considerable constancy of the temperature inside of the tube, where the variations did not exceed $\pm 1^\circ\text{C}$. The hydrogen was circulated over the sample and through the system (the total volume of which was about two liters) by means of a magnetically operated glass propeller C.

Samples of the gas were taken from time to time through the stopcock D with an evacuated 20 ml or 50 ml burette, and the H₂S present absorbed in 2 pct zinc acetate solution. The volume of the remaining hydrogen was measured, temperature and barometric pressure noted and the volume reduced to standard conditions.

The hydrogen sulphide was determined iodimetrically. Either micro-

burettes or 50 ml burettes were used. In the case of the microburettes, the samples were made up to 100 ml with 2 pct zinc acetate solution. An aliquot was acidified with 1.0 ml of glacial acetic acid, titrated with an excess of 0.002 N iodine and back-titrated with 0.002 N thiosulphate. The 50 ml burettes were used when the hydrogen sulphide content of the sample had to be determined as a whole in one analysis. The procedure was the same with the exception of making up to the volume. In either case, the 0.002 N solutions were prepared daily from stock solutions of 0.1N iodine and 0.1 N sodium thiosulphate, and the sodium thiosulphate was standardized with the 0.002 N iodine. The range of hydrogen sulphide content in samples was from 0.015 mg per 100 ml to 1.255 mg per 100 ml. The mean precision was ± 3 pct.

The equilibrium was approached from both sides (excess of H₂ and excess of H₂S). The excess of H₂S was obtained in the following way. The equilibrium ratio H₂S/H₂ increases with temperature; therefore, to raise the concentration of H₂S the sulphide was heated in H₂ up to a temperature higher by a hundred or more degrees than the temperature of the intended measurement and, after the equilibrium had been reached, the temperature was lowered as quickly as possible to the intended level.

Fig 2 gives an example of approaching the equilibrium at 900°C from both sides.

The equilibrium with FeS and Cu₂S was usually reached in less than 24 hr. With MnS, however, four to six days were required to obtain equilibrium and, contrary to the behavior of the other two sulphides, high temperature did not reduce the time needed for the equilibrium to be established. In some runs at temperatures over the melting point of Mn, the sulphide sample was examined after the reaction; its grains were covered with a compact layer of metallic manganese. This layer probably contributed to the difficulty of free diffusion of H₂ and H₂S and to the slowness of the reaction at high temperatures.

The reliability of the results would be expected to depend greatly on the suppression of side reactions, especially between the gas mixture and the refractory furnace tube. This was checked by using different tubes (quartz, mullite, and alundum) at temperatures below 1200°C. No notice-

FIG 2—Approach to equilibrium H_2S/H_2 ratio for FeS at $900^\circ C$.

able influence of the kind of refractory material used (or of the presence or absence of Apiezon) on the values of the equilibrium ratio H_2S/H_2 was observed. Quartz tubes, however, crystallized and developed leaks. Even the high quality alundum tubes lost their impermeability to gases, especially at temperatures above $1200^\circ C$, and many runs had to be discarded because of the diffusion of air into the reaction tube. It is known that the presence of H_2S facilitates the reduction of SiO_2 .⁵ The siliceous binding material of the alundum or the silica itself, in the case of quartz, is apparently attacked by this means. Mullite tubes, although they contain silica, withstood the severe conditions to a much better extent than either quartz or alundum, and were used for most of the runs.

Experimental Runs

Table 1 gives a comparison of the $\log H_2S/H_2$ equilibrium values for the reaction $FeS + H_2 = Fe + H_2S$ found by Jellinek and Zakowski, Britzke and Kapustinsky, and in the present investigation. The column "Calc. Kelley" contains Kelley's data, computed from the thermodynamic properties and regarded as quite reliable. It may be seen from Table I that our figures are much closer to those calculated by Kelley than are those of the other authors; the latter, in addition, are in considerable disagreement with one another.

Tables 2, 3 and 4 contain all experimental data for FeS, MnS, and Cu_2S , needed for the calculation of the equilibrium pressure of sulphur over the respective sulphides and of the free energy of formation of these sulphides.

In Fig 3, the values of the logarithm of the equilibrium S_2 — pressure over the sulphides is plotted against $1/T$. The points, though scattered a little, can be represented by straight lines, the slopes of which give the heats of formation of the respective sulphides if we regard this heat of formation (in the first approximation) as independent of the temperature:

$$\log_{10} P_{S_2} = \frac{\Delta H}{2.30RT} + C \quad [2]$$

To avoid any arbitrariness (due to the scattering of the points) in drawing the lines, the most probable straight lines representing the respective sets of points have been calculated, assuming that the error in $1/T$ was much smaller than the error in $\log P_{S_2}$.

For FeS the measurements were taken up to the melting point of the sulphide. Above this point the activity of the condensed components should be taken into account; this requires the knowledge of the actual composition of the liquid phase at the temperature of the measurement. However, as the study of the reaction with FeS was taken up mainly for the sake of comparison of our data with those of other investigators and for the sake of checking the precision which could be obtained, we did not attempt, for the present, to undertake these measurements.

With MnS the case is different. There is no appreciable solubility of

MnS in liquid manganese and therefore the activity of both MnS and Mn remains equal to unity above, as well as below, the melting point of manganese. The scattering of our points is too great to reveal, in a definite way, the effect of phase transitions on the slope of the $\log P_{S_2}$ vs. $1/T$ line. Therefore all points (up to $1583^\circ K$) were used in the calculation of the most probable straight line representing them.

The case of Cu_2S is, fortunately, simplified by the fact that, although we have two phases (Cu_2S —rich, and Cu—rich phase) in the liquid state, the mutual solubilities of the components are not very different, and change with the temperature in a roughly similar way. Thus the lowering of the activity of Cu is approximately compensated by the lowering of the activity of Cu_2S and consequently all the points within the whole range of temperatures in question lie on the same straight line.

Discussion of Results

From Fig 3 we see that the intersection of the Cu₂S-line with the MnS-line occurs at 1350°C. At this temperature both MnS and Cu₂S show the same decomposition pressure of sulphur or—what amounts to the same—both Mn and Cu have the same affinity for sulphur (their free energies of formation, $\Delta F^\circ = -RT \ln 1/P_{S_2}$, are the same), provided the activities of the condensed phases are the same. Above 1350°C the decomposition pressure of sulphur over MnS is greater, that is, the affinity of Mn for sulphur is smaller (*ceteris paribus*) than the affinity of copper for sulphur.

The log P_{S₂} vs. 1/T lines in Fig 3 can be expressed by the following equations:

for FeS

$$\text{Log } P_{S_2} = -\frac{17,810}{T} + 7.540 \quad [3]$$

for Cu₂S

$$\text{Log } P_{S_2} = -\frac{14,360}{T} + 3.721 \quad [4]$$

for MnS

$$\text{Log } P_{S_2} = -\frac{21,350}{T} + 8.029 \quad [5]$$

Because these equations refer to the reaction between gaseous sulphur and the condensed metal, the heats of reaction between gaseous sulphur and metal (referred to 1 mol S₂-gas) can be directly calculated from them. We then obtain:

for FeS $\Delta H = -81,990$ cal

for Cu₂S $\Delta H = -65,700$ cal

for MnS $\Delta H = -97,860$ cal

Regarding, in first approximation, these heats as independent of temperature we can subtract the heat of evaporation of rhombic sulphur and calculate the heats of reaction between

the respective metal and rhombic sulphur, referred to 1 mol of the sulphide. Taking for the heat of sublimation of rhombic sulphur 31,360 cal (from Kelley's paper quoted above) we obtain the following values:

for FeS $\Delta H = -25,060$ cal

for Cu₂S $\Delta H = -17,170$ cal

for MnS $\Delta H = -33,160$ cal

The figures thus found for FeS and Cu₂S are in reasonable agreement with the heats of formation experimentally

measured which range from -18,000 cal per mol to -24,000 cal per mol for FeS, and from -18,260 cal per mol to -18,970 cal per mol for Cu₂S. The experimentally found heat of formation of MnS is much more uncertain, the values ranging from -44,390 cal per mol to -62,900 cal per mol. From the aqueous solubility data of MnS⁶ a value of ca. -50,000 cal per mol may be calculated. One single point measured for the equilibrium of the reaction MnS + H₂ = Mn + H₂S by Jellinek and Zakowski⁵ allowed Kelley to calculate the ΔH of formation for MnS as ca. -35,000 cal per mol. The latter value is the nearest to that obtained by us. On the other hand, the error in the experimentally determined heat would work in the direction of higher values because even a slight oxidation would cause a relatively high heat effect. Therefore lower values seem to be more probable. On the whole, one has to remember that the thermodynamical data for the formation of MnS are still far from being settled.²

FIG 4—Variation of $-RT \ln P_{S_2}$ with T for MnS, FeS, and Cu_2S .

($\Delta F^\circ = -RT \ln P_{S_2}$) have been plotted against T . The slope of the curves

$$\frac{-\partial \Delta F}{\partial T} = \Delta S$$

represents the entropy

value, which is negative for the formation of the sulphides. The scattering of the points is too great, however, to make its calculation worth while. At any rate, it is evident from these curves and from the fundamental relationship

$$\Delta F = \Delta H - T\Delta S$$

that the entropy term ΔS for the decomposition reaction $2MnS = 2Mn + S_2$ has a larger positive value than for the reaction $2Cu_2S = 4Cu + S_2$, and is responsible for the relatively lower value of the free energy of the first reaction at high temperatures.

The results of the present investigation lead to the following practical conclusions concerning the connection between the amount of copper in the open-hearth furnace scrap and the sulphur content of the bath. Because of the relatively high affinity of copper for sulphur at high temperatures, metallic copper present in the scrap may be expected to pick up sulphur from the heating gases by binding it

into Cu_2S ; thus the sulphur content of the bath would increase with the copper content of the scrap and consequently the desulphurization process would be hampered.

The question remains whether the copper sulphide thus formed is preserved as such in the bath and furthermore, whether it still exists in the ingot after solidification. Though the authors are inclined—on the basis of other experiments—to believe that a comparatively large percent of total sulphur exists in finished steel as copper sulphide, they do not think that the present experimental results can be regarded as supporting directly this point of view. Until the equilibrium diagram Cu-Mn-Fe-S and the influence of other components on its shape have been investigated, no further conclusions can be drawn save that the free energy relations of FeS, MnS and Cu_2S in pure systems give a necessary (though not sufficient) support to the possibility of existence of large amounts of copper sulphide in finished steel.

Summary

The equilibrium constants of the reactions of FeS, MnS, and Cu_2S with H_2 were measured within a range of

temperature wide enough to establish the dependence of these equilibrium constants on temperature. The equilibrium pressures of S_2 over the respective sulphides and the free energy of formation of the sulphides were calculated therefrom.

The affinity of sulphur for copper (as measured by the free energy of formation of the sulphide) is considerably greater than that for iron and begins to exceed that for manganese at temperatures above $1350^\circ C$. It is concluded therefrom that metallic copper which is present in the scrap is to be expected to pick up sulphur from the open hearth furnace gases and thus raise the sulphur content of the bath.

Plastic Deformation Waves in Aluminum*

ANDREW W. McREYNOLDS†

Introduction

ONE characteristic of plastic deformation which distinguishes it from elastic strain is the essential inhomogeneity of plastic strains. Elastic strain varies continuously through a material, and average relative displacements of initially adjacent atoms are only small fractions of their initial spacing, (strains of the order of 0.01 or less). On the other hand, plastic flow corresponds to the appearance of discontinuities in strain of the lattice, such as dislocations or slip bands, where local strain, on an atomic scale, is several orders of magnitude higher. These discontinuities are visible on a microscopic scale as the familiar slip lines (Fig 1). In spite of this obvious microscopic inhomogeneity, however, macroscopic measurements almost invariably show a smooth curve of stress vs. strain (Fig 2b) even if measurements of linear strains be made to an accuracy of one part in 10^7 .

This macroscopic homogeneity of strain indicates that the discontinuities in strain on slip planes occur in increments too small or too slow to be recorded individually, and further that they occur sufficiently independent of one another so that the small increments add at random to a smooth stress-strain curve. The present paper describes observations of plastic strain in aluminum of commercial purity and in high purity Al-Cu alloys, where there exists a strong coupling between slip in various regions of the specimen such that once initiated it spreads rapidly through a large volume. The total effect is that of relatively large, rapid, and regularly spaced steps of strain followed by periods of only elastic strain. Fig 2a illustrates the type of "stair-step" stress-strain curve which results. The properties of this cooperative slip phenomenon will be described further in the section on results; in par-

ticular it will be shown that each step corresponds to the propagation of a wave of plastic deformation through the specimen. Some interpretations of the mechanism by which it occurs will be made in the following section.

Although the type of plastic wave phenomena to be described has not previously been reported, there are numerous cases of related effects in the plastic yielding of metals:

YIELD POINT PHENOMENA

The most familiar of such effects is the "yield point" observed in low carbon steels, brass, duraluminum, and the like. It consists in the sudden termination of the elastic portion of the stress-strain curve by a large plastic strain. Since the usual tensile machine is such that yielding of the specimen relieves the load, the resulting curve is as shown in Fig 3. As the strain continues, deformation occurs at a lower stress for some time, then follows a rising curve, but with no further sudden yielding. This effect has been observed in brass by Sachs and Shoji¹ and later by many others. Edwards, Phillips and Jones² made extensive studies of the effect in steel, and of the role of various alloying elements.

Although there seems to be fairly clear evidence that the yield point is caused by a hardening of the material by precipitation of impurities, no satisfactory explanation for the sudden yielding has been given. Winlock and Leiter³ have shown that the stress level of the upper yield point depends strongly on the rate of loading, the yield point increasing by almost a fac-

tor of two as the strain rate goes from 0.002 in. per in. per min. to 4.4 in. per in. per min. This effect would seem to imply an incubation period before yielding is initiated at a certain stress. On the other hand, by going to very slow loading rates, Edwards, Phillips and Jones² showed that the yield point does not become lower and eventually disappear as might be expected, but, on the contrary, begins to rise at loading rates below about 25 lb per in. per min. becoming much higher than at rapid loading rates.

STRAIN AGING

If, instead of continuing straining of a specimen after occurrence of a yield point, the load is removed and the specimen aged, resumption of the test results in occurrence of another yield point as shown by the dotted curve of Fig 3. The new yield stress is generally higher than the previous maximum applied stress. This hardening of the material by straining and subsequent aging is undoubtedly related to quench age-hardening resulting from the aging of a specimen quenched from high temperature. Since neither effect is observed in pure metals, it is generally accepted that quench-aging in all cases is the result of hardening by precipitation of a supersaturated alloying element, and that strain-aging is probably a similar precipitation, accelerated by disruptions of the lattice by previous strain. Pfeil⁴ has shown that strain-aging does not occur in iron from which all of the carbon has been removed, but that only a very small carbon content, around 0.003 pct, is necessary to cause strain-aging. In accord with this observation is recent work by Dijkstra⁵ in this laboratory showing that the solubility limit of carbon in iron is extremely low, less than 0.001 pct at 400°C. Edwards, Phillips and Jones² have shown that the strain-aging effect is also removed by the addition of small quantities of elements such as Mo, Mn, Ti, and the like, which readily form carbides. Their results demonstrate the

close relation between the yield point phenomena and strain-aging, since both of these effects are destroyed in the same way by addition of carbide forming elements. Their conclusion is that all of the carbon is bound in insoluble carbides and therefore not available for precipitation hardening. Kuroda⁶ has suggested that the yield point is caused by concentration of the carbon around the grain boundaries, forming a hard cementite sheath around each grain. When, at the yield point, this sheath breaks down, the stress during further yielding depends only on the ferrite interiors of the grains and is consequently lower (the lower yield point). It appears at present, however, that the yield point and strain-aging effects can be attributed to precipitation of carbon, but that the detailed mechanism of the precipitation hardening is still uncertain.

SERRATED STRESS-STRAIN CURVES

It has been observed that under some conditions the initial plastic portion of the stress-strain curve exhibits no yield point effect, but that after a small

plastic strain, a series of sudden yields occurs in rapid succession, resulting in a curve as indicated in Fig 4. This type of behavior has been reported in mild steel from 80–250°C by A. Le Chatelier,⁷ in mild steel at 250° by Körber and Pomp,⁸ and in duraluminum (Al-4.8 pct Cu) at room temperatures by Portevin and Le Chatelier.⁹ More recently Sutoki¹⁰ reported similar observations of serrated curves for steels up to 0.9 pct carbon at temperatures of 150°C and higher, duralumin at 20–100°C, 70/30 brass at 450°, and nickel at 300°. In all of these cases, however, strain was either at a relatively rapid rate, so that the observations were complicated by inertial effects and oscillations of the testing machine, or in a machine such that sudden yielding necessarily decreased the stress.

It is to be noted that the serrated curves occur in the same materials which exhibit yield point and strain-aging effects, but that the temperature ranges for the phenomena may differ. In iron, for example, the serrations occur only in an elevated temperature range, around 200°, whereas the yield point occurs at least as low as 20°. Edwards, Phillips, and Liu¹⁰ therefore

expected a yield point in duraluminum at subatmospheric temperatures, since serrations are exhibited at temperatures around 20°. Their tests showed no such yield point, although Sutoki's¹⁰ results show one case of a yield point at room temperature in a quenched and tempered duralumin sample.

LÜDERS' LINES

Lüders¹² reported in 1860 the appearance of large scale markings on the surface of strained mild steel sheet. These markings were later studied systematically by Hartmann¹³ and are well known as "Lüders' lines," stretcher strains, or Hartmann or Piobert lines, but are still only incompletely understood. In cylindrical or strip tensile specimens the "lines" appear as broad bands extending completely across the specimen, at angles of around 50° to the axis of tension, and are visible because the greater plastic deformation within the band causes a depression or change in orientation of the surface. The direction of the bands is determined by the geometry of the specimen and the applied stress, and a band may extend across a number of grains, independent of their orientation.

In mild steel specimens, as the yield point is reached, Lüders lines (or bands) appear on the surface and spread throughout the specimen as the yield point elongation takes place. As described by Fell,¹⁴ the spreading takes place at nearly constant stress, corresponding to the horizontal portion of Fig 3, following the yield point, and further strain within the band begins only after the surface markings have spread over the entire surface, at which time the stress-strain curve resumes an upward trend by strain hardening. The surface markings persist, however, presumably because of differences in the amount of yield point elongation in different bands.

Similar effects have been observed in duraluminum by Hartmann¹³ and more recently by Fell.¹⁵ Fell shows no photographs of markings in aluminum but describes them as a number of parallel bands (more regular than Lüders' lines in steel) inclined at about 60° to the specimen and tension axis and extending across the strip specimen. A photograph of such bands in 24 ST sheet is given by Stang, Greenspan, and Newman¹⁶ (their Fig 1). Fell also observed that a number of successive yields occurred with increasing stress and in each case an inclined

FIG 2—Curves for 0.500-in. diam cylindrical specimens loaded continuously at constant rate of 120 psi per min.

- (A) Typical step curve for 2S-Aluminum—measured over $\frac{3}{4}$ in. of gauge length.
 (B) Smooth curve for pure aluminum under same test conditions. Both removal of load and holding load constant cause slight yield point elongation.

straight line on the surface propagated from one end of the specimen to the other at velocity around 20 cm per sec. Each such yield represented only 0.5–1 pct strain, whereas in steel the yield point elongation is of the order of 5 pct. Portevin and Le Chatelier⁹ also reported that the serrated stress strain curves described above were characterized by the appearance of Lüders' lines on the surface and that each oscillation of stress was accompanied by propagation of the markings along the specimen with an audible "little dry noise."

REPEATED YIELDING

A number of cases of repeated yielding have been observed both at constant load and with increasing load.

Becker and Orowan¹⁷ found that zinc single crystals held at approximately constant stress in a Polanyi machine exhibited sharp steps of from 10^{-5} to 10^{-3} strain at irregular intervals, and

that a temperature increase of 10–20°C resulted in a great increase of frequency. Schmid and Valouch¹⁸ made similar observations. Measurements of creep rate at constant stress in high purity zinc by Tyndall and Wert¹⁹ showed alternate periods of very rapid and slow creep. Andrade²⁰ reported sudden yields at regular intervals in "approximately pure" copper under constant stress.

Classen-Nekludowa²¹ applied increasing shear loads to specimens of NaCl, brass, and aluminum, and found that yielding occurred in very regularly spaced and sharp steps, resulting in a stair-step type stress strain curve. It was found, however, that these steps occurred only in an elevated and limited temperature range, 230–500°C for NaCl, 410–550°C for brass, and 450–550°C for aluminum. Davidenkow²² later presented an interpretation of these results in terms of recrystallization.

The relation of the above repeated

yield phenomena, at nearly constant stress and at elevated temperatures, to the stair-step stress strain curves observed by the author is not readily apparent. An effect which is obviously closely related, however, is Fell's¹⁵ observation of a number of successive yields of duraluminum strip specimens. The resultant stress strain curve is of stair-step form, similar to those observed by the author. It seems likely also that the serrated stress strain curves shown in Fig 4 would also be in the form of rectangular steps if the loading were accomplished by a machine in which oscillations of stress are precluded.

The effects briefly discussed above: yield point elongation, serrated stress-strain curves, Lüders' lines, and stepped stress-strain curves (repeated yielding), have been arbitrarily divided in the discussion for purposes of clarity. It is desired, however, not to differentiate between them, but rather to point out that all appear to be manifes-

tations of the same effect, propagation of plastic deformation waves through the stressed medium. They have in common that:

1. All involve propagation of plastic deformation
2. The presence of certain impurity atoms in appropriate state of solution or precipitation is necessary
3. The required impurity atoms are those which result in quench or strain age-hardening (C in Fe, Cu in Al, Be in Cu)
4. Appropriate test conditions of temperature and loading rate must prevail, although these conditions may differ for the different effects.

The most plausible general hypothesis seems to be that the effect of the impurity atoms is to precipitate in such a manner as to harden the lattice against plastic deformation, and that such precipitation hardening facilitates propagation of the plastic waves. The present studies on the propagation of successive plastic waves in aluminum were made with the objective of further elucidating both the connection between these related phenomena, and the detailed mechanism by which they occur.

Apparatus and Procedure

STRAIN MEASUREMENT

The elongation of specimens was measured in all cases electrically by use of bonded resistance wire gauges similar to the commercial SR-4 gauge. Because of such factors as softness of specimens, diversity of gauge sizes and shapes, and necessity of rapid application, gauges were assembled directly on the specimen instead of gluing on commercial SR-4 gauges. The technique used was to glue on a layer of lens tissue with thinned Duco cement and lay on the paper 6 or 8 strands of 0.001-in. diam hard drawn advance wire, of total resistance 100 ohms, held by several coats of the same cement. The ends were then soldered to heavier wires, also glued to the specimen. Gauges of this type usually lasted to about 3 pct strain before the wire broke, and were sufficiently linear over this range. Calibration could be made by measuring specimen length before and after test. Because of softening of the Duco cement, however, these gauges were reliable only up to about 60°C. For higher temperatures the wires were mounted with DC-804 silicone resin supplied by the Dow-

FIG 3—Illustration of yield point phenomena as found in mild steel. Dotted curve shows effect of aging sample after initial strain.

FIG 4—Illustration of serrated stress-strain curve as found in mild steel at 250° or in duralumin at 20°C.

Corning Chemical Co. A thin coat of cement was baked on for $\frac{1}{2}$ hr at 200°C; the wires were then laid on and held by a special jig, covered by a second coat of resin and baked another $\frac{1}{2}$ hr. After removal of the jig a third coat was baked on. These gauges were found usable up to temperatures of 170°C, although some relaxing of the resin sometimes occurred, but the useful strain range was only of the order 1 to 1.5 pct.

The gauge constituted one arm of a Wheatstone bridge, with a second arm consisting of a dummy gauge on an aluminum rod in good thermal contact with the specimen, for temperature compensation. The other arms were dial resistance boxes. Current of the order of 25 ma from a storage battery was passed through each arm of the bridge. Instead of the usual null method of using a galvanometer as detector and repeatedly adjusting the resistors for balance, the resistors were left constant and the bridge unbalance recorded continuously on a Brown "Elektronik" strip chart self-balancing potentiometer with full scale range of 10 mv. Bridge current was usually adjusted so that full scale on the chart was about 1 pct strain, the smallest detectable strain being about 0.1 pct of the full scale, or 10^{-5} strain, although this sensitivity could be increased about five fold if desired. The

chart (see Fig 5) then represented a direct continuous plot of strain vs. time, or, as long as loading rate was constant, strain vs. stress. A chart speed of 30 in. per hr was convenient for most tests, but for rapid strains was increased to 1200 in. per hr, or 0.33 in. per sec.

For measurement of the time relation of strains in different parts of the specimen, four or five gauges were mounted at intervals along its length, each in a separate bridge circuit, and recording each on a separate potentiometer. For these measurements the recorder chart drives were speeded up to 0.33 in. per sec and the four charts were synchronized by periodic electrical pulses.

Since the steps encountered and time intervals between them were in many cases too rapid to be followed by the recording potentiometer, some tests were also made with a 12-channel photographic recording oscillograph with multi-channel amplifier for recording simultaneously the response of several gauges. In this case the bridge current was 5000 cycle ac from an oscillator contained in the amplifier unit, and response time was limited only by the natural frequency (1500 cycle) of the galvanometers. This equipment was kindly made available and operated by Mr. Petersen and Mr. Tahl of the General Motors Electromotive Div.

FIG 5—Typical chart record of strain vs. time curve for 2S aluminum at 25°C and continuous loading rate of 240 psi per min. Calibration represents 1 ohm change in one arm of bridge.

Photographic records are shown in Fig. 12.

LOADING APPARATUS

Instead of the standard type of "hard" tensile machine which increases strain at a constant rate, it was desired to have a constant rate of loading (approximately constant stress rate, since strains were small) and to maintain the load during yielding. A simple lever system as shown in Fig 6 was therefore set up. The entire apparatus was on a shock mounted table set on a spring supported concrete block, and the load was communicated to the lever through a soft spring which served the dual purpose of cushioning against external vibration or oscillation of stress during

yielding and of measuring the load by its extension. Load could be read to 0.1 mm on the spring scale, corresponding to 0.5 lb on the specimen. It was applied by draining water through a needle valve into a bucket hanging on the spring scale.

The specimens were turned from $\frac{3}{4}$ -in. diam rod to $\frac{1}{2}$ -in. diam, leaving a shoulder on each end, and were held in end blocks by a split collar arrangement on which the shoulders rested. Tension rods of $\frac{1}{4}$ -in. steel connected to the end block by a hardened ball and cone socket which allowed self-adjustment to axial stress.

Temperature was controlled by circulating alcohol for low temperature, or prestone for high temperature, through $\frac{3}{8}$ -in. copper tubing wound around and

soldered directly to the end blocks, the liquid being driven by a small centrifugal pump and cooled by passing through coils immersed in liquid nitrogen or a dry ice bath or heated similarly. Temperature differential between end blocks and specimen was always less than 2°C and much less except during rapid cooling or heating.

It is to be noted that the tensile testing procedure used differs from conventional engineering practices in several respects.

1. Load is applied by a dead-weight (soft) type of mechanism rather than by the usual (hard) tensile machine in which elongation is at a constant rate. In such a soft machine stress can be increased at a uniform rate since it is unaffected by yielding of the specimen.

2. The strain-sensitive element measures only a localized area of the specimen rather than averaging over most of the length of the specimen. Also the sensitivity, 0.001 pct, is considerably higher than most mechanical strain gauges.

3. A continuous recording of strain is obtained, as is essential for observing the type of small irregularities which were found in stress-strain curves.

ALLOYS USED

The 2S samples were ordinary commercial 3/4-in. rod. Pure aluminum copper alloys were made by melting in vacuum aluminum ingots of 99.996 pct purity, donated by the Aluminum Co. of America, with additions of electrolytic copper shot. The alloys were cast in molds 1 1/4 x 1 1/4 x 6 in. and cold rolled to 3/4 x 3/4-in. square bar, from which specimens were machined. Before testing, each specimen was annealed for 1/2 hr at 500°C in air and cooled to room temperature in a stream of air. Grain diameter of the resulting structure was about 0.1 mm. Chemical analyses of the samples used are given in Table I.

Results

GENERAL DESCRIPTION OF EFFECT

The general plastic properties have been observed from records of strain by single gauges of 3/4-in. length on specimens of 2S and Al-Cu alloys. In an annealed specimen of 2S at 25°C loaded at constant rate of the order of 200 psi per min. the initial portion of the stress-strain curve up to about 0.3 pct plastic strain is smooth. Waves then become perceptible on the record of strain and rapidly become sharper until the curve of strain vs. time assumes a stair-step form with rapid steps of strain (around 0.05 pct) occurring in times of a few seconds and sometimes of 0.1 sec, followed by periods of several minutes during which only elastic extension occurs (see Fig 5). The steps are not random but occur at regular stress intervals of about 250 psi, and adjacent steps represent approximately equal amounts of strain. Actually the spacing and size do not remain constant but become progressively larger with increasing stress, being about proportional to the total stress. Also with increasing stress (or strain) the corners of the

steps (in 2S Al) become progressively less sharp (see Fig 10, 14). In Fig 7 the height and length of steps is plotted against total stress.

In view of the differences in technique from conventional tensile testing procedure one test was conducted using an ordinary “hard” tensile machine, which operates at approximately constant strain rate, and which allows relief of stress when the specimen yields. Results (Fig 8) verified that the same phenomena occur, although the sharpness of steps is much decreased.

EFFECT OF STRUCTURE AND CHEMICAL COMPOSITION

Tests under similar conditions, and also over a range of temperatures and strain rates, were also performed on 99.996 pct pure aluminum, which was prepared by the Aluminum Co. of

America. Since the pure aluminum in all cases exhibited smooth curves rather than the anomalous curves of the type observed for 2S, anomalies of 2S could be attributed to an effect of the impurity content of the 2S (Cu, Fe, and Si, principally). On that basis copper was chosen as a suitable alloying element and alloys of the 99.996 aluminum with 0.025, 0.1, and 0.5 pct Cu were made up. The observed plastic properties were similar to those of 2S, except that: 1. Steps began at much smaller strains and the first ones are of much smaller size (see Fig 11). 2. Steps are much sharper in 0.1 and 0.5 pct Cu alloys than in 2S. In 0.025 pct alloys the steps are not sharp and appear only under some conditions of previous strain, loading rate, and others. 3. Temperature limits, as discussed below, are different.

The fact that copper content of 0.1 pct is much more effective than

FIG 7—Variation in size of steps with stress. Each curve applies to a single stress-strain curve and each point on curve corresponds to a single step. Horizontal axis is stress at which step occurred.

0.025 pct suggests that the phenomena may depend on precipitation from supersaturated solid solution. Extrapolation of 200–400° data on the aluminum-copper phase-diagram indicates a solubility at 25°C somewhat higher than 0.1 pct, but the solubility limit at this low temperature is rather uncertain. At first it appears surprising that 2S aluminum has less sharp steps than a pure Al-Cu alloy with less Cu content (0.1 pct). It has been shown, however, by Fink, Smith, and Willey²³ that the presence of Fe in Al-Cu alloys greatly decreases their capacity to age-harden, probably by removal of the copper from solid solution. Since Fe is the principal impurity in 2S aluminum, the effective Cu content is thus probably considerably decreased.

Grain size was found to have no profound effect on the qualitative features of the phenomenon although Fig 9 shows that the strength of the alloy is highly dependent on grain size. Note that the step size is greater in the smaller grained structure (where the stress is correspondingly higher) and that the smooth initial portion of the curve continues to greater strains the smaller the grain size.

PROPAGATION

Since continuous plastic flow is observed only until the beginning of the step phenomenon but then ceases, it must be concluded either that the entire region under the gauge remains

elastic except for periodic localized slip, or that each step corresponds to a plastic deformation of the entire region, but leaves it in a hard, elastic condition immediately afterward. Simultaneous measurements of several gauges on different parts of the specimen confirmed the truth of the latter supposition.

A large number of tests was made with multiple gauges along the length of the specimen, to investigate the nature and velocity of the propagating plastic deformation wave. The usual arrangement of gauges was four $\frac{5}{8}$ in. long gauges in a line parallel to the axis, with $\frac{1}{8}$ in. spacing between their ends. Fig 10 shows a typical combined record of four gauges. Although the time differences are barely perceptible on the time scale of Fig 10, steps did not occur simultaneously in all gauges but in rapid succession, and in sequential order. For example, steps would be recorded at intervals of around 1 sec successively on gauges 1, 2, 3, and 4, indicating that strain is initiated at one point and spreads throughout the entire specimen. Thus each step in the stress-strain curve may be considered as the propagation of a plastic deformation wave front along the specimen. It was to be expected that the point of initiation would sometimes lie between gauges and the wave front spread in both directions. It was actually observed that the order of appearance of steps was sometimes, for example, 2, 1, 3, 4, indicating initiation of strain between

FIG 8—Curve for 2S-Aluminum specimen in standard "hard" tensile test machine. (A) Strain vs. time curve from chart of automatic recorder (B) strain vs. stress curve plotted by combining curve (A) with data read from load dial of machine.

gauges 1 and 2. As strain increased, the steps became more rounded and had no well defined beginning or end (see last steps in Fig 10). Under these conditions it was difficult to distinguish any time difference between strains at different points, and the records showed about the same strain at all four gauges at any instant.

In other cases, however, particularly in Al-Cu alloys, deformation waves propagated only through a limited region of the specimen, then stopped. Strain in the adjoining regions also occurred by the periodic propagation of a wave, but at independent times. This behavior is illustrated in Fig 11. The sharp steps shown occurred at intervals of the order of two minutes, but in every case two or more gauges recorded steps either simultaneously or only a few seconds apart. In Fig. 11 the small numbers beside the four curves indicate relative time in seconds between strain steps which occurred at approximately the same stress. It will be seen that there is a repeated sequential order of occurrence 1-34 . . . 23-4 . . . 1-34 . . . and so on. (See particularly Fig 11 at stresses

(3) Grain diam 5 mm (much longer parallel to axis).
Steps begin later but are larger for small grain size.

2300–3300 psi.) This behavior indicates that each strain propagates through a limited region, that some gauges cover parts of separate regions, as designated by A, B, C, and D, and that the sequence of steps in these regions is A–C . . . B–D . . . A–C . . . B–D, and so on.

It can also be seen that appearances of deformation waves in regions A and C are always within a few seconds of each other, and likewise the times of waves in regions B and D are very close. The interaction between such separated regions evidently is not by passage of a plastic wave, however, since no strain is registered by the intervening gauge. The nature of the boundaries of the regions is not known, but as seen from the later steps of Fig 11, and as indicated by the dotted brackets, these boundaries are not entirely fixed but shift with increasing strain.

RATE OF PROPAGATION

The propagation velocity of the deformation wave can be measured roughly from its time of arrival at successive gauges. It was found that:

1. The velocity is relatively slow as compared to sound velocities for propagation of elastic waves, being of the order of a few cm. per second.
2. There

FIG 10—2S Aluminum specimen. Simultaneous records of four gauges arranged as shown along specimen. Sequential order of steps in gauges indicates plastic strain wave starts at one point and propagates through entire specimen.

FIG 11—Al-0.5 pct Cu specimen. Simultaneous records of four gauges $\frac{1}{2}$ in. long, $\frac{5}{8}$ in. center to center along specimen. Small numbers beside each step give time in seconds relative to other gauges. Analysis of times of steps in various gauges indicates each step corresponds to deformation throughout one of the regions A, B, C, or D.

is no unique velocity for aluminum or even for a particular composition of aluminum, such as 2S, the velocity depending strongly on the state of strain, and varying over a wide range during a single test.

The wide variation in propagation rate is illustrated by Fig 12. In 12a, all five gauges, ($\frac{1}{8}$ in. long and $\frac{5}{16}$ in. center to center) show steps in rapid succession at average intervals of about 0.01 sec, corresponding to 80 cm per sec velocity; but in 12d the time interval between gauges is of the order of 1 to 1.5 sec, or 0.5 cm per sec velocity. In general it was observed that the rate of propagation was very rapid for the sharp steps observed in pure Al-Cu alloys, all gauges showing steps within a 0.1 sec interval; the rate associated with the less sharp steps characteristic of 2S Al was much less, with intervals up to several

seconds between gauges. Under some conditions, however, 2S also exhibited sharp steps, in which cases propagation was rapid. It thus appears qualitatively that the velocity of propagation increases with sharpness, to a maximum of at least 80 cm per sec. This interdependence of sharpness and propagation velocity is partly but not entirely explained by the consideration that a slower wave front takes longer to traverse the gauge and thus results in a less sharp step. Reference again to the last few steps of Fig 10 shows that the steps have degenerated to rounded waves, but, since the waves are almost in phase, the propagation time must be short compared to the duration of a single wave. A sharp but slowly propagating wave would produce a record on which step 1 is completed before 2 starts, and so on.

Considering the plastic deformation

of the specimen as a plastic wave progressing through it, it is of particular interest to determine the shape of the wave front, that is:

1. Does the wave front advance continuously, with a smooth transition from zero to maximum strain or in discrete steps by the sudden appearance of strained slabs such as the Lüders' bands in mild steel indicate?

2. Is the wave front a plane surface inclined to the axis and along the direction of maximum shear stress?

3. Is the advancing wave front sharp, and does all of the strain occur immediately as it passes, or persist for some distance and time behind?

Some conclusions on point (3) may be drawn from interpretations of Fig 10-12. It will be noted that in the rapid steps of Fig 12 a, b, c, strain at each gauge continues for about 0.1 sec during which time the wave has propagated to all other gauges and thus a distance of several centimeters. Also the initial part of the step seems more rounded than accountable by time for the wave to traverse the $\frac{1}{8}$ -in. gauge. Likewise in the slower steps of Fig 10 and 12d strain continues at a given point long after the wave front has passed. In Fig 10 the length of the region undergoing strain and the time for which strain continues at a given point are both longer than for more rapid steps as in 12a, b, c. The results then lead to the concept of a continuously moving but not necessarily sharp wave of the type indicated in Fig 13.

Investigation of the plane shape, orientation, or continuity of motion of the wave front cannot readily be accomplished by multiple gauge techniques, first, because a large number of gauges of small area would be required and second, because lack of sharpness of the wave front makes precise time of arrival at a point difficult to determine. For this reason a visual or photographic method seems much more appropriate. Preliminary observations on strip specimens, 0.50×0.065 -in. cross-section, of 52 S-O aluminum (nominal composition 2.5 pct Mg, 0.25 pct Cr) show plainly visible bands appearing and spreading along the surface. In this case a narrow straight band, inclined 45-50° to the axis, suddenly appears and rapidly spreads in both directions, the advancing boundaries remaining quite straight and at the original orientation. The bands usually do not spread through the entire specimen. In 2S strip,

strain waves are accompanied by passage along the surface of a disturbance which is perceptible but not distinct enough to determine its shape, and in Al-0.5 pct Cu no surface markings are seen. These latter results are to be expected since the amount of strain per step is smaller than in 52 S-O, where it is 0.5–1 pct. Even in 52 S-O many steps are recorded by the strain gauge before they increase in size enough to be visible on the surface.

It thus can be considered probable that even in cylindrical specimens the wave front is a plane oriented approximately along the direction of maximum shearing stress. Further work is in progress on visual and photographic observations by improved techniques.

EFFECTS OF TEMPERATURE

By use of a liquid circulating system as described above, temperatures could be controlled within 1°C in the range

–60 to 170°C and could be altered within a few minutes without interruption of the test. It was found that the anomalous stepped stress strain curve appears only within a certain temperature range, becoming smooth again above or below that range.

For determination of the upper and lower temperature limits, a series of tests, each on a separate sample and at constant temperature, were made. The results for such a series on 2S aluminum are shown in Fig 14. It will be seen that as the temperature is decreased the step phenomenon begins at greater strains, until at about –20°C the entire curve is smooth except for occasional gentle ripples. On the other hand, increase of the temperature causes the steps to appear at small strains but to fade into a smooth curve, and at sufficiently high temperatures the entire curve is again smooth. Several tests were also conducted in which the temperature was alternately raised or lowered during

the course of the test, either while the load was constant, or without interruption of loading. One of these is shown in Fig 14 and is in agreement with the temperature limits indicated by the other curves. Because of the systematic change in the steps with increasing strain, however, this method was not used for determining temperature limits.

A similar series of tests on pure Al-0.1 pct Cu alloy gave a somewhat wider temperature range, but showed that the onset and termination of the steps is much more abrupt in this purer material. Instead of degenerating to rounded waves the steps give way abruptly to a smooth curve. Although the temperature ranges within which the steps occur are not well defined, they can be specified approximately:

| Material | Temperature Limits | |
|----------------------------|--------------------|----------|
| | Upper °C | Lower °C |
| 2S Aluminum..... | +60 | –10 |
| 99.99 Al + 0.1 pct Cu..... | 120 | +10 |
| 99.99 Al + 0.5 pct Cu..... | 150 | +10 |

EFFECT OF RATE OF STRESS

Several tests have been conducted with 2S specimens, where, without

FIG 12—Al-0.5 pct Cu specimen. Oscillograph records of strain at five gauge positions as shown in Fig 13.

- (A) Strains in rapid 1, 2, 3, 4, 5 sequence as plastic wave traverses specimen in about 0.05 sec.
- (B) Plastic wave apparently starts near gauge 2 and propagates both ways. Note that strain continues in gauge 2 after wave has advanced to gauge 4, and that wave stops abruptly before reaching gauge 5.
- (C) Plastic wave in region under gauge 1, then after 0.1 sec delay wave through region under 1, 2, 3.
- (D) Slowly propagating wave takes about 1 sec to traverse distance between gauges. Note that rate of strain is correspondingly slow.

FIG 13—Probable distribution of strain in plastic wave. As shown, slowly propagating wave has longer duration at a fixed point as a result of both low velocity and greater length. Bottom graph shows stress-strain curve which would result from repeated occurrence of such waves.

FIG 14—Stress strain curves at various temperatures in 2S Aluminum.

Temperature and loading rate, 120 psi per min, constant in each run, except first curve, where load was held constant for 6 min. during each temperature change.

otherwise interrupting the test, the loading rate has been suddenly changed from slow to rapid rates and vice versa. One of the resulting stress strain curves is shown in Fig 15. It is seen that the size of the steps is affected somewhat, but that variation in loading rate by a factor of 50 causes relatively small changes, less than a factor of 2, in step size and spacing. It is to be expected that the effect of rate may well be much greater near the upper or lower temperature limits, but as yet, the effect of loading rate has been investigated systematically only at room temperature.

In 0.025 pct Cu alloys it is found that steps in the curve appear only under certain conditions. In particular, the rate of loading must be sufficiently slow. This would indicate, in terms of the mechanism postulated in the following section, that with such low copper content, more rapid loading rates do not allow sustained steps because of insufficient time for precipitation hardening between strains.

EFFECT OF AGING AND HEAT TREATMENT

Since the effects observed are shown to depend on the presence of an alloying element in the aluminum and are probably the result of a supersaturated solid solution, appropriate aging or heat treatment might be expected to

affect the plastic properties by changing distribution of the solute atoms in solution, or in precipitation aggregates. The stress-strain curves were found to be unaffected, however, by the difference between a water quench from the annealing temperature of 500°C (which should result in maximum supersaturation) and relatively slow cooling from 500°C, followed by 20 hr annealing at 100°C (which should precipitate out the supersaturated solute atoms). Fig 16 shows the result of a test in which straining was interrupted at intervals for heat treatment. Effects of heat treatment were minor.

It has been observed, however, that specimens of 2S aged around 100 days at 25°C subsequent to annealing deform in sharper steps than those freshly quenched.

STEP PHENOMENON IN BRASS

Several other metals have been tested under conditions similar to the tests of aluminum. Cadmium and high purity copper exhibited only smooth curves, but annealed 70/30 alpha brass had a stepped stress-strain curve similar to those described above, with regular steps of around 0.5 pct occurring at stress intervals of around 150 psi. It was observed that the step phenomenon does not set in until strain of a few percent has occurred.

If the specimen is given a somewhat smaller strain and aged one or two days at room temperature, however, steps begin immediately when plastic straining is resumed. Otherwise no systematic study of the effect in brass has been made.

Discussion and Interpretation

Before attempting to make interpretations of the physical mechanism of the plastic effects observed, the qualitative general results may be summarized. These results apply to fully annealed cylindrical tensile specimens of 2S aluminum and of aluminum-copper alloys with 0.1–0.5 pct copper, strained at a constant rate of loading.

1. The elastic portion of the stress strain-curve is followed by a gradual and smooth plastic region up to 0.1 to 0.3 pct, followed by a short transition region in which the curve changes to the form of square steps of regular height and width. Subsequent deformation occurs almost entirely by steps, the size of which increase proportionally with the total stress. Some homogeneous creep may occur between steps, accelerating just before appearance of a step.

2. The steps are found to be the result of the initiation of plastic strain

at some region in the specimen and its propagation as a wave of plastic deformation along the length.

3. The plastic waves move at velocities up to a maximum of at least 80 cm per sec, the velocity being greater for sharper steps. They do not necessarily traverse the entire sample but may be stopped by structural barriers of undetermined nature. Plastic flow at a given point continues after the wave front has passed several centimeters beyond.

4. If aluminum free of impurities (99.996 pct pure) is used or if the temperature of test lies either above or below a certain range, -30 to $+60^{\circ}\text{C}$ for 2S, $+10$ to 120 – 150°C for Al-Cu alloys, deformation occurs not by the above step process but according to a smooth stress-strain curve.

5. Appearance of the steps is not greatly influenced by heat treatment of either strained or unstrained specimens, although prolonged aging of annealed 2S specimens results in somewhat sharper steps and aging of previously strained specimens decreases the sharpness.

On the basis of experimental results summarized above several postulates can be considered with regard to the physical mechanism by which plastic deformation occurs under these conditions. In this section they will be enumerated and the degree to which they provide an adequate interpretation of observed qualitative features of the phenomena discussed in each case:

1. The presence of alloying elements in aluminum is necessary to harden the lattice against continuous plastic flow between steps. The most probable mechanism by which such hardening is effected is by precipitation of the solute atoms on slip planes.

a. This postulate is based on the observation that pure aluminum (99.996 pct) exhibits a smooth stress-strain curve under conditions where Al-Cu alloys have anomalous curves.

b. Precipitation can occur in relatively short times even at room temperature as evidenced by the well known age-hardening effects of Al-Cu alloys. It should be men-

tioned, however, that extrapolation of higher temperature diffusion rate data would give diffusion rate at room temperature much too low to allow precipitation. It appears therefore that such extrapolation is not valid. In the present case it must be assumed that precipitation is greatly accelerated in the vicinity of slip bands where many lattice vacancies and imperfections exist.

c. Preferential precipitation on slip bands has been shown metallographically in Al-Cu alloys by Fink, Smith, and Willey.²³

d. If hardening is effected by precipitation, the steps would be expected to disappear as the temperature is decreased into a range where precipitation rate becomes too slow. This is in accord with observations that the steps do gradually fade and disappear over a temperature range from 0 to -20°C . (See Fig 14.)

2. Macroscopic steps in the stress-strain curve represent a cooperative effect between grains, by which relaxation on slip bands in one grain initiates slip bands in adjacent grains.

a. Thus plastic deformation occurs as a wave propagating from grain to grain.

b. On a larger scale the wave spreads through large regions of the metal, as a front usually extending entirely across the specimen, as observed both visually and by simultaneous recording of strain at several points on the tensile specimens.

3. Initiation of new slip bands in adjacent grains depends on building up of stress concentrations at the edges of slip planes or, viewed on a larger scale, ahead of an advancing deformation wave front. Consequently, under conditions where continuous relaxation is occurring (on previously formed slip bands or at the grain boundaries), the resultant relief of local stresses may prevent high concentrations, thus preventing propagation of a deformation wave.

a. Disappearance of stress-strain curve steps at higher temperatures (around 60°C for 2S aluminum, 120 – 150°C for Al-Cu alloys of 0.1–0.5 pct Cu) may be explained as a result of the increased creep rate in that range, since creep at constant stress becomes appreciable in roughly the same temperature ranges. The upper temperature limit for appearance of steps has been found to depend not only on temperature but on the amount

FIG 15—Effect of variation of load rate in 2S Aluminum.

Load applied continuously but with abrupt changes of rate as indicated.

FIG 16—Effect of aging at elevated temperature—2S Aluminum.

(A) Entire tensile test conducted at 25°C but interrupted for 20 hr aging at 100°C. (B) All strain at 25°C except as indicated near end of curve.

and rate of previous plastic strain. That is, at higher temperatures, steps fade at smaller strains. (See Fig 14).

- b. An alternate explanation of the high temperature disappearance of the step phenomenon would be that as solubility increases with temperature a point is reached where the solid solution is no longer supersaturated and therefore does not precipitate. On this basis, however, one would expect widely different upper temperature limits for 0.1 pct Cu and 0.5 pct Cu and also an appreciable effect of heat treatment such as 20 hr aging at 100°C. Since neither of these predictions is found true, it seems unlikely that solubility determines the temperature range for steps.

- c. In all cases where loading was stopped and stress held constant for several minutes, further loading produced a period of elastic strain followed by a sharp and unusually large step of plastic deformation. The same effect was observed under conditions where no steps would otherwise occur (that is, in 99.99 pct pure aluminum or in Al-Cu alloys or 2S aluminum above or below the temperature range for step deformation). In the latter cases, however, step deformation did not persist but rapidly faded. These observations may be explained by the fact that holding stress constant for several minutes allows

cessation of transient creep and thus makes possible enough stress concentration for strain to be propagated from grain to grain as a deformation wave.

- d. It was frequently observed that, in a specimen being loaded at constant rate but at a temperature high enough to give a smooth stress-strain curve, a sudden decrease of temperature of only a few degrees produces a step in the curve. In this case also deformation soon reverts to a smooth stress-strain curve. As demonstrated by Carreker, Leschen, and Lubahn²¹ recently, such a sudden drop in temperature in a stressed material creeping at constant rate momentarily stops all creep, but creep resumes after a short incubation time. Thus immediately after a decrease in temperature the rate of stress relief by creep is low enough to permit propagation of a plastic wave but resumption of creep prevents successive waves.

4. Only a small amount of relaxation in a grain just at the advancing deformation wave front is necessary to initiate plastic slip in adjacent grains ahead of it.

- a. Waves have been observed to propagate with velocity varying over rather wide limits but with maximum around 80 cm per sec. This relatively slow velocity (as compared with the sound velocities for propagation of elastic waves) indicates that there is a

slight delay in transmission of slip from grain to grain, and such a delay would be expected while relaxation on slip bands in one grain proceeds far enough to build up stress sufficient to initiate new bands in the adjacent grain (or to reactivate slip on old bands).

- b. It would be expected that where continuous creep is occurring simultaneously with step deformation, a greater amount of relaxation would be necessary to initiate plastic strain in the next grain and consequently the rate of propagation would be slower. Comparison of different samples indicates that the less sharp the steps (that is, the more continuous creep) the lower the propagation velocity.
- c. It is found in Al-Cu alloys that deformation at one point of a specimen (or more accurately in a region under a 3-mm long gauge) continues after the wave front has travelled 5–10 cm beyond. The strain occurring as the wave front passes is only a small part of the total, and further strain at the point continues at a decreasing rate.

Although the above four postulates represent a fairly consistent outline of the mechanism of transmission of the plastic deformation waves, some observed properties which are not completely explained by the postulates should be discussed. In general, their explanation requires more detailed knowledge of the mechanism, and of

the dynamics of slip bands. Some aspects of the latter subject are to be discussed by C. Zener in the October 1948 ASM symposium on plastic deformation.

1. The steps are not of random size but occur at uniformly increasing stress intervals, approximately proportional to the total stress, and result in uniformly increasing amounts of strain. Further, both beginning and termination of the steps are in many cases sharp. A complete theory of the phenomena must therefore include both an explanation for the uniformity of stress increments between steps and a mechanism by which the deformation in single grains, once started, is terminated sharply at a definite strain value. A balance between these two factors then determines average slope of the stress-strain curve.

2. The exact mechanism by which the alloying elements effect hardening of the lattice to prevent plastic flow is not definitely known. Although it probably results from precipitation of aggregates of copper on the slip planes, it is difficult to picture a precipitation effect which occurs within the 0.1 second duration of the strain in such a way that precipitation hardening terminates the strain at a fixed value. It seems more plausible that each step results in complete relaxation across some slip planes, further strain being prevented by constraints of surrounding regions. Precipitation hardening on that plane then has time to occur before arrival of another deformation wave results in yielding elsewhere, again bringing stress across the same plane.

Summary

1. Plastic deformation of 2S aluminum and Al-Cu alloys is found to proceed according to a stair-step stress strain curve rather than at a continuous strain rate. The same effect is observed in 70/30 alpha brass.

2. The discontinuities are found to result from propagation of waves of plastic deformation along all or part of the specimen length; between occurrence of such waves practically no plastic strain occurs. Under varying conditions waves may be either very sharp or extended and velocities range

from a few millimeters to around 100 cm per sec. Duration of the corresponding strain steps may vary from 0.1 sec to around 1 min.

3. The effect is found to depend on presence of an alloying element such as Cu or Mg in aluminum, and does not occur in 99.99 pct aluminum.

4. Dependence of the phenomenon on such parameters as temperature, amount and rate of strain, and heat treatment or aging has been studied, with results as summarized in the section on discussion. Of particular significance is the fact that the effect does not occur except in a limited temperature range (-10 to 60°C for 2S).

5. The type of deformation observed takes place by appearance of slip bands, but differs from the more usual type in that slip on individual bands is not independent; strain, once initiated, spreads to adjacent grains.

6. It is pointed out that yield point elongation, serrated stress-strain curves and Lüders' or Hartmann lines are examples of a similar propagation of plastic waves. Furthermore, all of these effects have in common that they appear to depend on precipitation hardening.

7. The proposed mechanism for the observed phenomenon of repeated plastic waves may be summarized as follows: Motion on slip bands during strain results in lattice vacancies and imperfections which greatly accelerate general diffusion and precipitation of copper aggregates in the immediate vicinity. Consequent precipitation hardening stops all relaxation on the bands. When stress eventually increases enough to initiate further slip at some point, the hardened condition of the lattice causes high stress concentrations in the vicinity, which facilitate spread of the strain into adjacent grains. As successive grains break down under the stress concentrations, a wave of strain spreads through the metal and is followed by further precipitation hardening, thus starting a new cycle.

Acknowledgments

The author wishes to acknowledge indebtedness to many of the staff of

the Institute for the Study of Metals, particularly Professor C. Zener for stimulating discussions, Mr. David Houghton for carrying out many of the measurements, and Mr. John Gault for technical assistance; and also to Mr. Petersen and Mr. Tahl of the General Motors Electromotive Division for equipment and cooperation in making oscillograph measurements.

On the Structure of Gold-silver-copper Alloys

JOHN G. McMULLIN* and JOHN T. NORTON*

Introduction

THE ternary system of gold-silver-copper is characterized by a solid solubility gap and a two phase region in which copper-poor and silver-poor phases coexist. At about 30 pct gold, the two phases become mutually soluble at temperatures below the melting temperature. As the gold content is increased, the solubility temperature of the alloys decreases until at about 80 pct gold, the two phases are soluble down to the lowest temperature at which the alloys will recrystallize.

Although the general form of the two phase region is known, its boundaries do not seem to have been investigated extensively. In an X ray diffraction study, Masing and Kloiber¹ have outlined the boundaries of this two phase field at 400 and 750°C. Using only microscopic techniques, Pickus and Pickus² determined a vertical section of the ternary diagram showing the 14 kt alloys (58.3 pct gold). These two reports are not in complete agreement.

It has been shown³ that some of the ternary alloys are susceptible to age hardening and that the hardening is caused by the separation of a homogeneous alloy into two phases at the aging temperature. While the gold-copper binary system is an outstanding example of super lattice formation, Hultgren⁴ has shown that a few per cent of silver added to gold-copper destroys the tendency for ordering. Because of the age hardening possibilities of these alloys, it seemed advisable to investigate the boundaries of the two phase field more in detail using an X ray diffraction method, so as to permit a better understanding of the aging phenomena and enable predictions as to the behavior of other alloys to be made. This is especially true for the 18 kt alloys (75.0 pct Au) at the lower temperatures since they are known to exhibit age hardening.

Experimental Procedure

Twelve ternary alloys were prepared having the compositions shown in Table 1 and graphically in Fig 1. The gold used was fine gold bars supplied by Handy and Harmon. The silver was a bar of high purity silver from the U. S. Bureau of Standards. The copper was a bar of vacuum-treated, high conductivity copper from the National Research Corporation.

Table 1 . . . Composition of Alloys

| Alloy No. | Composition by Weight Per Cent | | | Solution Temperature °C | Lattice Constant of Solid Solution Angstrom Units |
|-----------|--------------------------------|--------|--------|-------------------------|---|
| | Gold | Copper | Silver | | |
| 1 | 58.33 | 3.00 | 38.67 | 350 | 4.054 |
| 2 | 58.33 | 5.00 | 36.67 | 475 | 4.037 |
| 3 | 58.33 | 10.00 | 31.67 | 570 | 3.999 |
| 4 | 58.33 | 20.83 | 20.84 | 640 | 3.918 |
| 5 | 58.33 | 30.00 | 11.67 | 590 | 3.859 |
| 6 | 58.33 | 36.67 | 5.00 | 390 | 3.810 |
| 7 | 58.33 | 38.67 | 3.00 | 350 | 3.807 |
| 8 | 75.00 | 20.00 | 5.00 | | 3.914 |
| 9 | 75.00 | 12.50 | 12.50 | 380 | 3.966 |
| 10 | 75.00 | 5.00 | 20.00 | | 4.033 |
| 11 | 65.00 | 17.50 | 17.50 | 550 | 3.938 |
| 12 | 70.00 | 15.00 | 15.00 | 475 | 3.954 |

The pure metals in the form of powder were weighed out in proper proportions and melted in graphite in a

high frequency induction vacuum furnace. They were heated to 1100°C and slowly cooled. The ingots were then removed from the crucible, inverted, returned to the crucible and remelted. This remelting procedure was intended to reduce segregation in the ingots. After remelting, the ingots were checked for weight loss. The weight loss in each ten gram ingot was held to less than 25 mg. The remelted ingots were cold rolled and then given a homogenizing heat treatment of 16 hr at 760°C to remove any remaining segregation.

Powder specimens were prepared by cutting the ingots with a fine file, one half the required amount of powder being taken from each end of the ingots. When the X ray diffraction pattern showed any difference in lattice constant between the ends of the ingot, the ingot was remelted and given an additional homogenization treatment.

All powder samples were sealed in evacuated pyrex tubes for heat treatment. Ordinary pyrex proved satisfactory for temperatures up to 650°C but above that temperature it was necessary to use a special high temperature pyrex glass. Annealing at temperatures below 500°C was done in a salt bath whereas for temperatures of 500°C and above an electric muffle furnace was used. In both furnaces the temperature control was $\pm 5^\circ\text{C}$. In all annealing treatments samples of cold worked powder were placed in a furnace which was already at temperature. In this manner the specimens recrystallized directly to the equilibrium structure for that temperature. Time at temperature was selected so as to allow complete recrystallization, but very little grain growth. Specimens were quenched from the annealing temperatures by breaking the pyrex tubes in cold water.

X ray diffraction photograms were made of all the heat treated powders using copper radiation and a Phragmen

focusing X ray camera. All the structures observed were face-centered cubic with no indication of ordering or tetragonality. The lattice constants of the phases were determined to ± 0.002 Å based on a copper K alpha one wavelength of 1.54050 Å. In alloys where the pattern of the solute phase was weak this accuracy was not maintained. Also alloy No. 9 did not recrystallize completely when annealed below its solution temperature and its lattice constants were not accurately determined. Since each alloy was annealed at several temperatures above its solution temperature the lattice constants of the solid solutions listed on Table 1 are the average of several determinations and are probably accurate to ± 0.001 Å.

Determination of Phase Boundaries

In order to determine the limits of the two phase field, the twelve alloys listed in Table 1 and plotted in Fig 1 were employed. Cold worked powder specimens of each alloy were annealed at several temperatures and quenched to room temperature. The lattice constants of each specimen were determined by X ray diffraction methods. For each alloy a plot was made of the lattice constant vs. annealing tempera-

ture. Fig 2 is typical of the twelve plots made in this manner. This plot shows the lattice constant of the gold-copper rich matrix phase as well as the larger lattice of the gold-silver rich solute phase. The diffraction pattern of the solute phase is very faint in some alloys, especially at temperatures just under the solution temperature. In alloys No. 1 and 7 the solute phase is present in such a small amount that it gives no visible diffraction pattern. In all alloys the variation in the lattice constant of the solvent phase is so large that the solution temperature can easily be determined. In Fig 2 the lattice constant of the alloy is constant for all temperatures above the solution temperature and decreases as the gold-silver rich phase is precipitated at temperatures below the solution temperature. The exact solution temperature is determined graphically by drawing a vertical line through the points above the solution temperature and the best smooth curve through the points below the solution temperature. The intersection of the vertical line and the curved line determines the solution temperature for the alloy in question. The solution temperatures of ten of the twelve alloys were determined in this manner. The solution temperatures of alloys No. 8 and 10 were below the lowest temperature at which these alloys would recrystallize.

Alloys No. 1, 2, 3, 4, 5, 6 and 7 all lie on one vertical section through the ternary system while alloys No. 9, 12, 11 and 4 lie on another perpendicular to it. These two sections are shown on Fig 3 and 4 where the solution temperatures of the alloys are plotted against their compositions. Using these two vertical sections and the silver-copper binary diagram, it was possible to sketch in the limits of the two phase region at several temperatures in the ternary system as shown in Fig 5.

Results

Fig 5 shows horizontal sections of the ternary diagram outlining the two phase field at five different temperatures. Each section is drawn from three points in the ternary field and two points taken from the binary copper-silver diagram. It is estimated that the error in the position of these boundaries is of the order of ± 2 pct in composition. Fig 4 shows a vertical section for equal parts of copper and silver in the range from 50 to 100 pct of gold.

The horizontal section at 400°C is in good agreement with the results obtained by Masing and Kloiber.¹ The vertical section corresponding to the 14 kt alloys is only in fair accord with the results of Pickus and Pickus² but these investigators presented their results only as approximations.

The horizontal section at 350°C extends into the region of the 18 kt alloys and thus shows how these alloys are susceptible to age hardening by transformation from a single homogeneous phase into two separate phases of different composition.

Acknowledgments

The authors wish to express their indebtedness to Messrs. Leach and Christie of Handy and Harmon for providing the pure gold used in the present investigation, and to Mr. Albert Mahfuz for performing much of the experimental work.

Stress and Strain States in Elliptical Bulges

C. C. CHOW,* A. W. DANA,* AND G. SACHS†

Introduction

A GREAT number of the investigations on the plastic flow of metals have been concerned with the establishment of a "universal" stress-strain relation. In such a relation some stress function when plotted against a strain function should yield identical curves for the various stress states.

In the first investigation of this type, Ludwik and Scheu¹ plotted the maximum shearing stress as a function of the maximum principal strain. Later Ros and Eichinger² introduced two universal stress-strain relations, the one relating the maximum shearing stress to the maximum shearing strain, and the other relating a stress invariant, suggested by von Mises and Haigh, to the corresponding strain invariant. (In more recent investigations the stress and strain invariants are frequently supplemented with some factor to render their meaning more lucid.) A further suggestion which has not attracted appreciable attention is that by Baranski³ who used stress and strain deviators.

The most common means of experimentation to determine the relation between stress and strain consists in subjecting thin walled tubes to combined internal pressure and axial tension.^{4a,4b,4c} This method allows the study of plastic flow under stresses which are variable in two directions. However, the plastic flow which can be obtained in this manner is comparatively small, being limited by either tension failure or instability.

For copper,^{4a} only the relation between maximum shearing stress and maximum shearing strain yielded good agreement. On the other hand, tests on a steel^{4b} and on an aluminum alloy^{4c} resulted in systematic deviations if any of the discussed universal stress-strain relations were used. It would seem, therefore, that the agreement mentioned above for copper is only incidental and explained by its high rate of

strain hardening compared to that of other metals.

Much larger strains than experienced in the tube tests can be obtained by subjecting a thin membrane of a ductile metal, which is restrained at its periphery, to a uniform hydraulic pressure. The thin sheet forms a deep bulge before it fails. The stresses and strains in such a bulge increase with increasing distance from the edge of the clamping "die," the maximum stresses and strains occurring at the pole (crown) of the bulge. While the stress and strain states are determined by the contour of the bulge, the absolute magnitude of the stresses and strains depends upon the hydraulic pressure. The bulge contour is in turn correlated with the geometry of the die opening.

The deformation and fracture characteristics of circular bulges, that is, bulges formed with circular clamping dies, have been the subject of numerous experimental and analytical investigations.^{5,6,7} It has been shown that plastically deformed circular bulges develop large and comparatively uniform strains before failure by instability^{6b,6c,6d} and closely assume a spherical shape.^{6d} Also the distribution of strains across the contour of the bulge is dependent on the metal being investigated and is correlated with, but cannot be predicted from, the metal's stress-strain characteristics.

On the other hand, oblong or elliptical bulges, that is, bulges formed with elliptical clamping dies, are not as susceptible to analytical analysis and have not been investigated to the extent that circular bulges have. The few available data^{6a,7c} indicate that stress states are obtained at the poles of the bulges, varying between plane strain and balanced biaxial tension, depending upon the geometry of the die opening.

In this paper, the strain state and curvatures exhibited by three bulge shapes, a circular and two elliptical bulges, Fig 1, are analyzed experimentally using methods described in previous publications.^{6a,6c} An attempt is made to derive the stress-strain relations for these bulges, which represent strain states in which the ratio of the two positive principal strains varied between 1.0 and 0.35. In addition, tension tests yielded data for a value of -0.5 for this strain ratio.

Such an analysis should indicate the applicability of the various laws correlating stress with strain to the stress and strain states occurring in bulged shapes.

Definitions and Nomenclature

The definitions of the major stress and strain quantities used in this paper are as follows:

s_1, s_2, s_3 = principal normal stresses

$$s_1 > s_2 > s_3$$

t = shear stress

e = conventional (unit) strain

$$\epsilon = \ln(1 + e)$$

$\epsilon_1, \epsilon_2, \epsilon_3$ = principal natural strains

γ = shear strain

The maximum shear stress:

$$t_{max} = \frac{s_1 - s_3}{2}$$

Frequently, the flow stress, $s_1 - s_3 = 2t_{max}$, rather than the maximum shear stress is used.

FIG 1—Typical shapes formed on hydraulic bulging of thin sheets.

The largest principal natural strain, ϵ_{max} , is the value of the principal strain having the largest absolute value.

The maximum shear strain:

$$\gamma_{max} = \gamma_2 = \epsilon_1 - \epsilon_3$$

The effective stress:

$$\bar{s} = \frac{1}{\sqrt{2}} \sqrt{(s_1 - s_2)^2 + (s_2 - s_3)^2 + (s_3 - s_1)^2}$$

The octahedral shearing stress, t_{oct}

$$= \frac{\sqrt{2}}{3} \bar{s}$$

The effective strain:

$$\bar{\epsilon} = \frac{\sqrt{2}}{3} \sqrt{(\epsilon_1 - \epsilon_2)^2 + (\epsilon_2 - \epsilon_3)^2 + (\epsilon_3 - \epsilon_1)^2}$$

The octahedral shearing strain, γ_{oct}

$$= \sqrt{2} \bar{\epsilon}$$

The factors in the equations for the effective stress and effective strain serve to render $\bar{s} = s_1$ and $\bar{\epsilon} = \epsilon_1$ for uniaxial tension ($s_2 = s_3 = 0$ and $\epsilon_2 = \epsilon_3 = -\epsilon_1/2$).

Material and Procedure

Cartridge brass (70 pct copper, 30 pct zinc) sheet of 0.040 inch thickness was chosen for the experimental investigation. The rolling and annealing schedule for the sheet was designed to produce isotropic material. To further insure uniformity, the sheet was annealed at 850°F for one-half hour and then air cooled.

In order to determine the degree of isotropy in the sheet, tension tests (specimens $\frac{3}{4}$ in. in width with a 5-in. gauge length) were made parallel to, transverse to, and 45° to the rolling direction. The three stress-strain curves were found to be identical, Fig 2. In Fig 3, the natural strains, ϵ_2 and ϵ_3 , from two series of tests are plotted as a function of ϵ_1 . It is seen that the sheet conforms reasonably to isotropic conditions.

Before bulging, the blanks were photogrided⁸ with a 20 line-to-the-inch net, the grid being parallel and perpendicular to the rolling direction of the sheet.

In all, six bulge shapes were made by using appropriate clamping dies. There were two circular bulges, two ellipses* with a ratio of minor to major axis of 0.60 and two ellipses* with this ratio 0.32. (See Fig 1.)

The equipment and procedure for testing bulges and measuring the pertinent quantities have been described in previous publications on circular bulges.^{6c, 6d} Each bulge was loaded in steps and unloaded after each step. The pressure was recorded and the principal strains and the height

* These contours were not exactly true ellipses but were bulged using clamping dies whose openings were constructed by using arcs of circles. See Ref. 6e for die geometry.

of the bulge surface at various distances from the pole determined.

The strains were measured along the two lines of the photogrid, which were initially located parallel to the short and long axis of the die. Over a considerable area in the center of the bulge, the strain values represent, with sufficient accuracy, the two principal strains in the bulge surface along its intersections with planes containing the pole and the major and minor axis of the die, respectively. Examples of the distribution of these strains are given in Fig 4 and 5. These graphs illustrate that the elliptical bulges exhibited a rather narrow region in the vicinity of the pole in which the strains were nearly constant. As to be expected, the strains decreased rapidly with increasing distance from the pole in the direction of the small axis, but only slowly in the direction of the large axis of the die.

The strain values at the pole obtained from the trend curves in Fig 4 and 5 are taken as the two principal strains, ϵ_1 (perpendicular to major axis) and ϵ_2 (perpendicular to the minor axis), for the respective load value.

Fig 6 and 7 illustrate distributions of the strain state, defined by the ratio of

FIG 4—Distribution of strains (ϵ_1 and ϵ_2) at various pressures for annealed 70-30 brass bulged to elliptical contour (ratio of minor to major axis = 0.32).

FIG 5—Distribution of strains (ϵ_1 and ϵ_2) at various pressures for annealed 70-30 brass bulged to an elliptical contour (ratio of minor to major axis = 0.60).

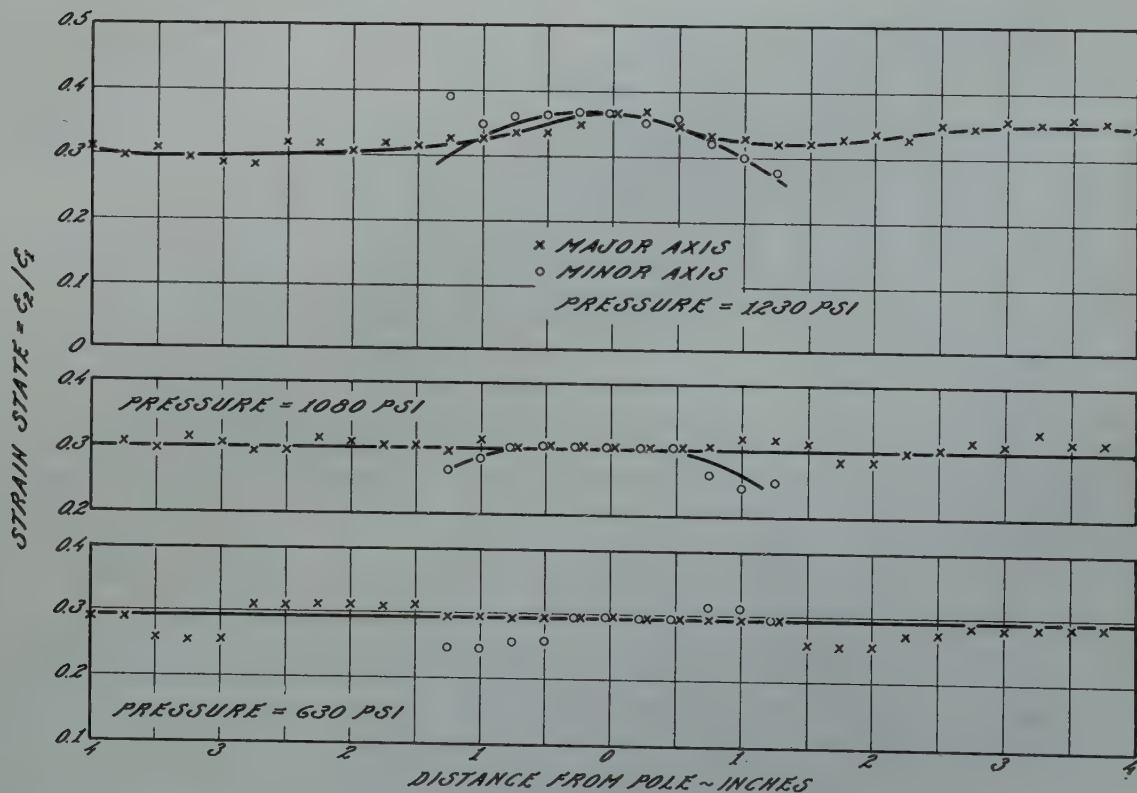

FIG 6—Distribution of strain state (ratio: ϵ_2/ϵ_1) in annealed 70-30 brass bulge (ratio of minor to major axis = 0.32). Derived from Fig 4.

the two principal strains in Fig 4 and 5. According to these graphs, the strain state differed only slightly over the crown of the bulge surface while large variations were noted in areas in the vicinity of the clamped edge.

The radii in the two principal directions of a bulge were determined from the height for various chord lengths, as described in a previous publication.^{5d} An example of the results of this procedure, for a few selected load readings, is shown in Fig 8. The values of the radii extrapolated to zero chord length are considered to be the radii of curvature at the pole, R_1 and R_2 in the two principal directions.

Since the bulge shapes were not fractured (only the one bulge having a ratio of minor to major axis of 0.32 was taken to fracture) it was possible to section the bulges for tension tests. These tension specimens were cut from the center portion of the bulges along the minor axis so that the pole was included. The additional strain resulting from the tension test was measured by using a radial strain gauge. In all cases no appreciable load was carried by the specimen until the specimen had straightened.

FIG 7—Distribution of strain state (ϵ_2/ϵ_1) in annealed 70-30 brass. Bulge (ratio of minor to major axis = 0.60). Derived from Fig 5.

Results

The bulging data are illustrated in Fig 9 to 12. The pressure, p , is plotted against each of the three principal strains ϵ_1 , ϵ_2 , and $-\epsilon_3$ in Fig 9 to 11, and the radii against the largest principal strain, $-\epsilon_3$, in Fig 12.

The values of ϵ_2 and ϵ_1 are replotted in Fig 13 as functions of $-\epsilon_3$. This graph reveals that during the forming of each bulge the strain state remains practically constant.

For the further analysis, average values of the various quantities obtained from the trendline through the experimental points for the two parallel tests are used. In general, for identical conditions two tests yielded results in close agreement.*

Analysis

The equilibrium of a shell element, Fig 14, yields the following relation:

$$\frac{p}{h} = \frac{s_1}{R_1} + \frac{s_2}{R_2} \text{ or } s_1 = \frac{R_1 p}{h} - \frac{R_1 s_2}{R_2} \quad [1]$$

* In the case of the elliptical bulges having a ratio of minor to major axis of 0.32 some deviation in the values was noted. This probably was due to the considerable slippage during one of the tests. However, this difference was found to be of little influence on the results of the analysis.

The experimental data yield the quantities p , h , R_1 , and R_2 . This leaves two unknowns for which only one equation is available. The other equation must be obtained from some established law of plasticity.

In this analysis the following assumptions will be made concerning conditions at the pole of the bulges:

1. Volume changes can be neglected during plastic flow, or:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \quad [2]$$

2. Stress states encountered during bulging are practically biaxial, or:

$$s_3 \approx 0 \quad [3]$$

3. Edge effects are negligible as are any bending or flexural stresses.

EFFECTIVE STRESS AND EFFECTIVE STRAIN

A relation, which is widely accepted, states that the second stress invariant is a function only of the second strain invariant and is independent of the stress state. Thus, for a given value of $\bar{\epsilon}$, the value of \bar{s} is given by the curve for balanced biaxial tension, in Fig 15. The definition of $\bar{\epsilon}$, Eq 4, and the constant volume condition, Eq 2,

$$\bar{\epsilon} = \frac{\sqrt{2}}{3} \sqrt{(\epsilon_1 - \epsilon_2)^2 + (\epsilon_2 - \epsilon_3)^2 + (\epsilon_3 - \epsilon_1)^2} \quad [4]$$

yield values of $\bar{\epsilon}$ for the various bulged shapes, corresponding values of ϵ_1 and

FIG 8—Example of determination of radii of curvature at pole for elliptical bulge (ratio of minor to major axis = 0.60).

FIG 9—Hydraulic pressure as a function of the three principal natural strains at pole for circular bulging of annealed brass sheet.

FIG 10—Hydraulic pressure as a function of the three principal natural strains at pole for elliptical bulging of annealed brass sheet.

ϵ_2 being determined experimentally. For these data Fig 9 to 12 then give the pressure, p , and the radii of curvature, R_1 and R_2 , and the value of \bar{s} which is defined as follows:

$$2\bar{s}^2 = (s_1 - s_2)^2 + (s_2 - s_3)^2 + (s_3 - s_1)^2 \quad [5]$$

Simplifying Eq 5 for bulges, where $s_3 \approx 0$:

$$\bar{s}^2 = s_1^2 - s_1 s_2 + s_2^2 \quad [5a]$$

Now by letting $c_1 = \bar{s}$, $c_2 = \frac{R_1 p}{h}$ and $c_3 = \frac{R_2}{R_1}$ and substituting Eq 1 in Eq 5a, a quadratic equation for s_2 is obtained:

$$s_2^2 - s_2 \left[\frac{2c_2 c_3 + c_2}{c_3^2 + c_3 + 1} \right] + \left[\frac{c_2^2 - c_1^2}{c_3^2 + c_3 + 1} \right] = 0 \quad [6]$$

from which:

$$s_2 = \frac{2c_2 c_3 + c_2}{c_3^2 + c_3 + 1} \pm \sqrt{\left[\frac{2c_2 c_3 + c_2}{c_3^2 + c_3 + 1} \right]^2 - 4 \left[\frac{c_2^2 - c_1^2}{c_3^2 + c_3 + 1} \right]} \quad [6a]$$

The corresponding value of s_1 may be obtained by substituting the value of s_2 in Eq 1.

The above calculations were carried out for the two elliptical bulges. However, the value of the ratio of s_2/s_1 were found to be approximately 0.55 in the case of the ellipse with a ratio of minor to major axis of 0.60 and 0.40 in the case of the ellipse with a ratio of 0.32. These values of the ratio s_2/s_1 are not consistent with the experimentally determined strain state. Apparently

the effective stress-effective strain relation is not sensitive to small changes in stress states.

ST. VENANT'S RELATION

An alternative method to determine the stresses present in elliptical bulges, from Eq 5, is to use as the second equation some relation between the known strains ϵ_1 , ϵ_2 , $\epsilon_3 = \epsilon_1 - \epsilon_2$ and the stresses s_1 , s_2 , $s_3 \approx 0$. Such a relation has been suggested by St. Venant. Previous investigations have shown that St. Venant's relation can be used to determine accurately the strains resulting from a varying stress state, such as occurs in deep drawing.⁹ Because of the consistent strain state, $\epsilon_2/\epsilon_1 = \text{constant}$, found to exist in

bulges according to Fig 13, St. Venant's relation also applies to finite strains, rather than to strain rates, as follows*:

* The validity of St. Venant's relation has been investigated repeatedly.^{4,9,10} It can be derived from this data that in the range of strain states occurring in bulging, namely, $\epsilon_1 > \epsilon_2 > 0$, the stress ratio s_2/s_1 may be actually as much as 5 pct larger than that given by St. Venant's relation. However, a correction of this magnitude would change the stress, s_1 , calculated from Eq 8 by not more than one to two percent. A correction of this magnitude does not affect the conclusions derived from the present investigation.

$$\frac{s_1 - s_2}{s_2 - s_3} = \frac{\epsilon_1 - \epsilon_2}{\epsilon_2 - \epsilon_3} \quad [7]$$

yielding for bulging, $s_3 = 0$:

$$\frac{s_2}{s_1} = \frac{\epsilon_2 - \epsilon_3}{\epsilon_1 - \epsilon_3} \quad [8]$$

For the two elliptical bulges investigated, where $\epsilon_2/\epsilon_1 = 0.60$ and 0.36 , respectively (Fig 13), this yields $s_2/s_1 = 0.85$ and 0.70 , respectively. Introducing these values into Eq 1 then permits calculating s_1 for these two bulges from the known quantities represented in Fig 9 to 12, according to the following respective relations:

$$s_1 = \frac{p}{h} \left(\frac{R_1 R_2}{R_2 + 0.85 R_1} \right) \quad (9a)$$

and

$$s_1 = \frac{p}{h} \left(\frac{R_1 R_2}{R_2 + 0.70 R_1} \right) \quad (9b)$$

The results of these calculations are shown in Fig 15, \bar{s}_1 being plotted against the largest principal strain, $-\epsilon_3$. In Fig 16, $s_1 = s_1 - s_3 = 2t_{\max}$ and \bar{s} are replotted as a function of the maximum shearing strain, $\gamma_{\max} = \gamma_2 = \epsilon_1 - \epsilon_3$, and Fig 17 illustrates the relation between s_1 and \bar{s} for the bulges investigated. The corresponding curves for the circular bulges (and also for uniaxial tension) are added to Fig 15 to 17.

The final results of the bulging tests on brass, represented in Fig 15 to 17, agree closely to those of the tests on

FIG 11—Hydraulic pressure as a function of the three principal natural strains at pole for elliptical bulging of annealed brass sheet.

FIG 14—Stress, strain, and geometrical conditions in an elliptical bulge.

FIG 15—Maximum stress (s_1) as a function of the maximum natural strain ($-\epsilon_3$ at pole for bulges and ϵ_1 for tension test) for annealed 70-30 brass tested under various stress states.

FIG 16—Maximum stress (s_1) and effective stress (s) as a function of maximum shear strain (γ_2) for bulge series and tension test on annealed 70-30 brass (values for bulges at pole).

FIG 17—Maximum stress (s_1) and effective stress (s) as a function of effective strain (ϵ) for bulge series and tension test on annealed 70-30 brass (values for bulges at pole).

copper tubes. Of the various types of stress-strain curves, only the relation between the largest principal stress (or more generally between the maximum shearing stress) and the maximum shearing strain yields identical curves for the three bulges investigated, within the limits of experimental accuracy. As discussed in the introduction, this agreement is not universal but appears to apply only to metals with a high rate of strain hardening. The simplest representation of the largest principal stress as a function of the (absolutely) largest principal strain yields, for stress states approaching plane strain, stress values as much as 10 percent higher than for balanced biaxial tension. On the contrary, the effective stress-effective strain ($\bar{s} - \bar{\epsilon}$) relation yields for conditions near plane strain, lower values of the stress invariant than for balanced biaxial tension.

Thus, none of the universal stress-strain relations proposed to date applies accurately, in the range of biaxial tension.

UNIAXIAL AND BIAXIAL TENSION

In order to establish any law of plasticity, some simple stress state must be selected as a basis. In the present investigation, two such stress states were investigated, uniaxial tension, $s_2 = s_3 = 0$ and balanced biaxial tension, $s_2 = s_1$, $s_3 \approx 0^*$ (present in circular bulging).

While any of the recognized theories of plasticity requires identical stress-strain curves for these two stress states, the present tests yielded according to Fig. 15 to 17 considerably higher stresses for balanced biaxial tension than for uniaxial tension.

As mentioned in the procedure the various bulges were sectioned and the strips tested in tension. The results of these tests are shown in Fig 18. The flow stress shown by these specimens closely approximated values expected if the metal had been prestrained in tension. It would seem, therefore, that

* In these tests the pressure did not exceed 1500 psi while s_1 was then almost 100,000 psi. Therefore, s_3 did not exceed one percent of s_1 .

some effect or effects other than anisotropy or stress state, must be operating to cause higher stress values in bulging. One of these effects might well be the nonuniformity of strain values over the bulge contour induced by the lateral restriction of the sheet. In other terms, non-homogeneity of strain in a structure results in higher values for plastic flow than would be called for by the common laws of plasticity. If this effect is sufficient to cause the noted difference between bulging and tension, it would be expected that the amount of this discrepancy would vary with the degree of nonuniformity of the strain.

The main objective of the present tests was to compare the stress-strain relations for bulges of various shapes. Therefore, for the foregoing analysis the stress-strain curve for balanced biaxial tension, where s_1 is given as a function of $-\epsilon_3$, was used as a basis. Between the various investigated bulges the degree of lateral restriction should be approximately the same and since the metal can be considered identical, the observed differences in the stress-

FIG 18—Results of tension tests on pieces sectioned from the various bulges. (The maximum strain in bulging is $-\epsilon_2$, while in tension ϵ_1 is used).

strain curves must be a result of the applied laws of plasticity.

Conclusions

Summarizing the results of this investigation, the following conclusions may be drawn regarding stress and strain states in elliptical bulging:

1. Stress values in elliptical bulges may be analyzed by using St. Venant's law of plasticity and the equation for equilibrium of a shell.

2. Stress states varying between balanced biaxial tension and close to plane strain can be obtained by bulging thin sheet using the proper die geometry.

3. None of the universal stress-strain relations proposed to date applies accurately in the range of biaxial tension.

4. The discrepancy between bulging and tension values of the stress required for plastic flow may be due to the non-homogeneity of strain across the contour of the bulge.

Acknowledgments

The authors are indebted to Mr. W. F. Brown, Jr. and Mr. F. C. Thompson for their help in formulating the program and to Mr. M. F. Jones for his aid in the experimentation.

A Study of Textures and Earing Behavior of Cold-rolled (87-89 pct) and Annealed Copper Strips

MING-KAO YEN*
Junior Member AIME

A CONSIDERABLE amount of work has been reported in the literature in regard to the texture and earing behavior of copper strip. The rolling texture of copper has been confirmed as (110) $\bar{1}\bar{1}2$ and (112) $11\bar{1}$, which yields ears of a drawn cup at the position 45° from the rolling direction.¹⁻³ The recrystallization texture has been established as the cubic or (100) [001] texture, where the earing positions are at 0° and 90° to the rolling direction.⁴⁻⁸ It has also been reported that in the development of cubically aligned grains of copper strips, the percentage of this cubic texture increased with an increase of final reduction and final annealing temperature.^{8,9} A comprehensive study on H.C. copper (British commercial copper of high-conductivity quality = Cu 99.95 pct, O₂ 0.03 pct, Ag 0.003 pct, Fe 0.005 pct and Pb < 0.001 pct) was made by Cook and Richards.⁶ They concluded that the recrystallization textures could be described as one or more of the following textures: (1) a single texture (100) [001], (2) a twin texture (110) $\bar{1}\bar{1}2$ and (3) a random orientation, depending upon the previous history of the specimen concerned.

The effect of various alloying additions in copper was reported by Dahl and Pawlek.¹⁰ They found that certain alloying additions, such as 5 pct Zn, 1 pct Sn, 4 pct Al, 0.5 pct Be, 0.5 pct Cd, or 0.05 pct P suppressed the formation of cubic texture. Brick, Martin and Angier¹¹ reported that the cold rolled textures due to various additions fitted a rather simple pattern. However, the recrystallization textures were subject to very considerable variations. In the discussion of this paper, Baldwin stated that deoxidized copper containing 0.02 pct P gave a complicated recrystallization texture at lower temperature. When this copper was annealed at high temperature, a single texture appeared which was described as (110) $\bar{1}\bar{1}1$ but, according to a pri-

vate communication from Baldwin, this orientation reported was in error and should have been reported as (110) $\bar{1}\bar{1}2$. He also reported that the earing positions of drawn cups were at 60° to the rolling direction.¹²

Recently, Howald, in his discussion on the paper by Hibbard and Yen,¹³ reported that the rolling texture of phosphorus deoxidized copper, containing from 0.006 to 0.020 pct phosphorus, was of the pure copper type. When these coppers were annealed at lower temperatures, they exhibited a random orientation, and when they were annealed at higher temperatures they had a mixed (111) $\bar{1}\bar{1}0$ and (100) [001] texture, depending on the severity of the final reduction and annealing temperature.

However, the specific influence of phosphorus and other impurities on the recrystallization textures and the deep drawing properties of copper strip has not been thoroughly reported. Therefore, an attempt has been made in the present work to determine the rolling and recrystallization textures and also the earing behavior of five types of commercial copper and thereby to evaluate the effect of phosphorus and some other significant impurities on the development of texture for cold reductions of about 87 to 89 pct.

Materials Used

The five types of copper employed in the present investigation were two phosphorus deoxidized coppers of different phosphorus content (0.007 and 0.013 pct P), an oxygen-free copper (OFHC), an electrolytic tough-pitch copper, and a fire-refined tough-pitch copper. These materials were subjected to a thorough spectroscopic and

chemical analysis. The designations and the chemical compositions were as shown in Table 1.

The coppers, FA1, FA2 and FA3, were hot-forged from 3-in. billets into a $\frac{1}{2} \times 6$ -in. plate and cold rolled to the ready-to-finish gauge indicated below. FA4 and FA5 were hot rolled and scalped to ready-to-finish gauge. The grain size of all the materials in the ready-to-finish condition was about 0.030 to 0.045 mm. Table 2 shows the last stage of the production schedule for each copper strip used.

Experimental Procedure

ANNEALING, GRAIN SIZE AND HARDNESS DETERMINATIONS

Specimens of each type of copper were finally annealed in air for periods of one hour at temperatures ranging from 300 to 1600°F and were subsequently cooled in air. The average grain diameter of the annealed specimen was estimated by comparing with a standard grain size chart. Hardness was determined on the Rockwell 15 T scale.

CUPPING TESTS

Cups were made in a blanking and drawing set, in which blanks of 2-in. diam were drawn to a cup of 1.25-in. diam with an average depth of about 0.75 in. The clearance between the punch and die was about 0.032 in. The ears of the cup were measured with a special fixture which read the height of ears to one-thousandth of an inch on every ten-degree interval along the circumference of the cup.

POLE FIGURES

The usual transmission diffraction method with unfiltered copper radiation was employed to determine the pole-figures of the specimens cold-rolled or annealed at 900°F. All the pole-figures were derived from the positions of intensity maxima on 111 diffraction rings of the X ray photographs taken at 10° rotation of a

San Francisco Meeting, February 1949.

specimen about its rolling and transverse directions. For specimens annealed at the higher temperatures, a structure integrating camera constructed by Wilson and Brick¹⁴ was used. The camera was designed to cover a specimen area of about 1.5 × 3 cm. The specimens were etched with 50 pct HNO₃ to a thickness of about 0.004 in.

GLANCING PHOTOGRAMS

Photograms obtained with a glancing X ray beam were used to detect the presence of cubically aligned grains and to evaluate the change in recrystallization textures. The X ray beam was directed at an angle θ to the rolling plane and in the transverse plane, where θ is Bragg's angle for the radiation used. By applying Bragg's law, $n\lambda = 2d \sin \theta$, the wavelength of Cu-K α radiation, λ is 1.537 Å, the interplanar distance of the (100) plane of copper, d , is 3.608 Å and for the second order of reflection, $n = 2$, the Bragg angle for 200 diffraction will be about 25°.

Fig 1a and b shows the ideal orientations superimposed upon the outline of the (111) and (100) pole figure of cold-rolled copper.^{3,15} The shaded arc at the vertical position represents the portion of 111 and 200 Debye-Scherrer rings produced in the glancing photograms. It will be seen that both 111 and 200 rings pass nearly through the center of the projection. Therefore, any grains with (111) or (100) planes present in the rolling plane will reflect to the center of the arc of the 111 or 200 diffraction rings, respectively. In addition, these

111 and 200 rings also cross the first order intensity regions of the deformation texture so that any grains in the deformation texture would most probably be detected.

The specimens were etched with 50 pct HNO₃ to a thickness of about 0.015 in., so that any defects or inhomogeneities on the surface could be eliminated. The specimen was then mounted on the goniometer with the rolling direction normal to the X ray beam and the rolling plane inclined at an angle of 25° to the beam. The optimum expo-

sure time was found to be a total of 10 min. with a potential difference of 35 PKV and a current of 10 ma. Similar photograms were also taken by using the structure integrating camera on the samples annealed at 1400 and 1600°F, where the grain size was found to be too large for the setup used for the lower temperature specimens.

Discussion of Results

Fig 2 shows the Rockwell hardness and the average grain size of the five types of copper strips as annealed one hour at various final annealing temperatures. The presence of phosphorus appears to contribute to the grain growth at higher temperatures. The higher softening temperature of specimen FA1, which contained 0.013 pct P, is also quite evident. These results are in good agreement with the work reported by Webster, Christie and Pratt on drawn wires.¹⁶ For the fire-refined copper, FA5, grain growth was suppressed to some extent and a slight effect on the softening temperature was noticed.

The results of the cupping tests and the glancing photograms of each specimen as cold-rolled or annealed at various temperatures are shown in Fig 3 and 4. Specimen FA1 showed no change of earing position at lower temperatures, while at higher temperatures the ears shifted from 45° to an angle of 40° from the rolling direction. Specimens FA3, FA4 and FA5 showed a typical behavior of copper, in that the ears occurred at the 0°-90° position and the earing height increased with the increase in annealing temperature. The earing position of specimen FA2 was somewhat complicated. It appeared that there were two transition zones, at 450° and 1400°F, where the earing position changed from 45° to 0-90° and returned to the 45° position when annealed at 1600°F. Referring to the glancing photogram, Fig 4, some correlation between the earing position and the grain orientation is noticeable. In the series of glancing photograms of

FIG 1—Ideal orientations superimposed upon the outline of the (111) and (100) pole-figures of cold-rolled copper.

FIG 2—The effect of final annealing temperatures on hardness and grain size of five different types of copper strips.

FA1, the grain exhibited a rather random pattern at 600°F, at which temperature the height of ears was a minimum. A small amount of cubically aligned grains was observed, however. As the preferredness gradually developed the cubically aligned grains diminished and a corresponding increase in the height of the ears was noticed. In specimens FA3, FA4 and FA5 the concentration of cubically aligned grains was found to be considerable even at lower temperatures, while the degree of preferredness of cubic

texture increased with increasing annealing temperature. Similar results were also observed in specimen FA2, annealed at lower temperature.

However, for specimens annealed at 1400 and 1600°F some uncertainties were aroused due to the larger grain size with accompanying lack of definition of these Debye-Scherrer rings. Thus, two series of photograms were taken by the integrating camera as shown in Fig 5. It was noted that, for specimen FA2 annealed at 1400°F, the pattern showed that the grains

possessed certain definite preferred orientations in spite of the fact that practically no ears were observed in the drawn cups. This leads to the assumption that the effect of the presence of the cubic texture which yielded ears at 0° and 90° and that of the other textures yielding ears at 45° were just balanced, so that the resultant effect on ears was neutralized. This assumption was also proposed by Howald¹⁷ in regard to 95-5 Cu-Zn alloy. He found that this alloy with 20 pct cubic texture and 80 pct of (113)[211] plus

FIG 3—Ear contour on cups drawn from five types of copper strips annealed one hour at the temperatures indicated.

FIG 4—Glancing photographs for five types of copper strips annealed one hour at the temperature indicated. Photographs reduced to one-half the original size.

FIG 5—Glancing photograms taken by structure integrating camera for specimens annealed one hour at 1400 and 1600°F.

(11 $\bar{5}$)[321] produced a cup of no ears. Furthermore, for the same specimen annealed at 1600°F, the decrease in the amount of cubic texture resulted in a change in the position of the ears to 45° from the rolling direction.

The pole figures of specimens in the cold-rolled condition were substantially the same as reported by previous investigators.^{3,7,11} The major orientations can be described as (110)[$\bar{1}12$] + (112)[11 $\bar{1}$]. Fig 6 *a*, *b* and *c* shows the rolling texture of specimens FA1, FA3 and FA5. Greater spread of the distribution of (111) planes on the pole-figure of specimen FA1 was noticeable.

Pole figures of all specimens annealed at 900°F were made (Fig 7). No appreciable difference was found between specimens FA2, FA3, FA4 and FA5. The annealing textures were composed of a strong (001)[100] texture superimposed on the retained rolling textures with a mixture of minor orientations (124)[53 $\bar{3}$], (110)[$\bar{1}12$] and (112)[11 $\bar{1}$]. These orientations have been reported as the three important ones in cold-rolled copper.³ In phosphorus deoxidized copper (0.013 pct P), FA1, a somewhat random recrystallization texture was obtained which may be described as a texture composed of (112)[11 $\bar{1}$], (110)[$\bar{1}12$] and (100)[001].

For specimens annealed at higher temperatures, the pole figures were de-

rived from photograms taken by the integrating camera. Fig 8*a* shows the texture of FA1 annealed at 1600°F which can best be described as (112)[11 $\bar{1}$] + (110)[100]. However, no texture of the type (111)[$\bar{1}10$] or cubic orientation¹³ is noticeable. Referring to the photograms of specimen FA1 at 1400 and 1600°F in Fig 5, the absence of (100) or (111) pole in the rolling plane is quite evident. For specimen FA2, annealed at the same temperature, a mixture of textures (113)[$\bar{2}11$], (110)[$\bar{1}12$], and (100)[001], was found. The pole figure of specimen FA3 annealed at 1600°F was similar to that obtained at the lower temperature, except that the intensity of the residual deformation texture decreased to a certain extent. The annealing texture may be stated as a strong (001)[100] texture with a weak (124)[53 $\bar{3}$] texture. For specimens FA4 and FA5, the secondary intensity of the deformation textures was further diminished, and a single texture of (001)[100] was approached. The pole figures were practically the same as reported by the previous investigators.^{7,11}

Several micrographs have been prepared along the rolling plane of specimens FA3, FA4 and FA5 (Fig 9). The specimens were polished and deeply etched with a potassium bichromate solution. The white matrix with two

FIG 6—(111) pole figures of cold rolled copper strips.

sets of twin bands at 45° to the rolling direction indicates the grains to be in cubical alignment. It can be seen that there is a certain amount of dark grains other than cubic ones still existing in specimen FA3, whereas for specimens FA4 and FA5, the cubic texture is practically 100 pct.

The effect of phosphorus on the electrical conductivity and softening temperature of copper is well known. The work of Hanson, Archbutt and Ford¹⁸ is typical. They found that the

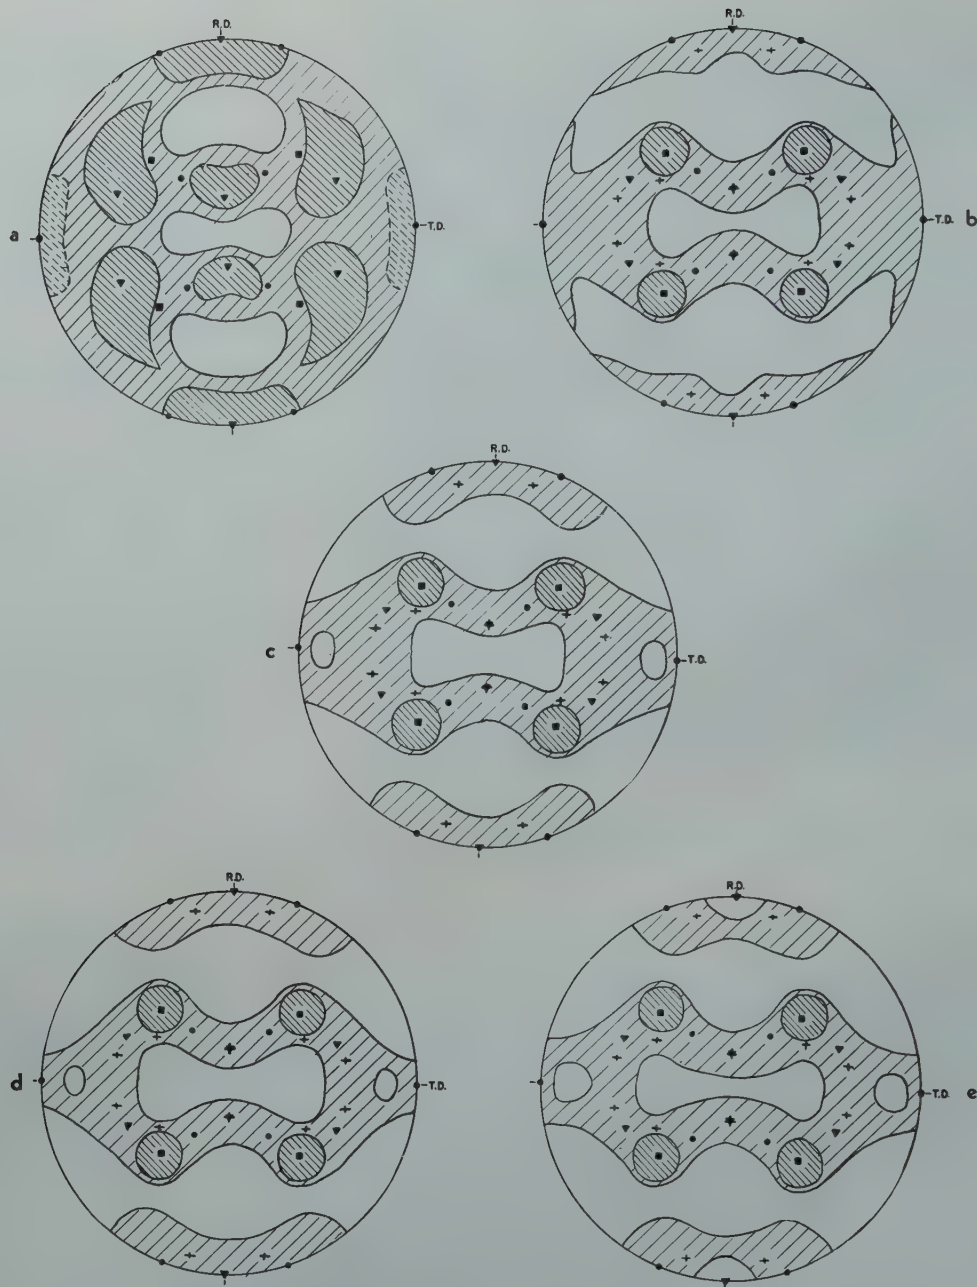

FIG 7—(111) pole figures for cold-rolled copper strips annealed at 900°F for one hour.

e. FA5—fire-refined. Ideal orientations indicated as follows: ■ (100)[001], ● (110)[$\bar{1}12$] ▼ (112)[11 $\bar{1}$], + (124)[53 $\bar{3}$].

addition of phosphorus yielded a marked increase of softening temperature and a marked decrease of electrical conductivity. Recently, Smart and Smith,¹⁹ stated that phosphorus when present in copper may be either in solid solution or in the oxidized condition. However, only the presence of phosphorus in solution has an important effect on the softening temperature and electrical conductivity. Thus, by comparing the conductivity measurement of specimens FA1, FA2 and FA3 with the results obtained by interpolating from the curves given by Smart and Smith,¹⁹ the following table is obtained.

Table 3 . . . The Effect of Phosphorus on Electrical Conductivity and Softening Temperature of Copper

| | Phosphorus Content pct | Electrical Conductivity pct IACS | Softening Temp. °C |
|-----------------------|------------------------|----------------------------------|--------------------|
| Oxygen-free Alloys | 0.013 | 93.0 | 305 |
| | 0.007 | 97.2 | 292 |
| | 0.0002 | 102.3 | 182 |
| Oxygen-bearing Alloys | 0.013 | 102.1 | 140 |
| | 0.007 | 102.2 | 140 |
| | 0.0002 | 102.3 | 140 |
| FA1 (Phosphorized) | 0.013 | 94.6 | 295 |
| FA2 (Phosphorized) | 0.007 | 101.4 | 170 |
| FA3 (OFHC) | <0.0003 | 101.3 | 200 |

The electrical conductivity of specimens FA1, FA2 and FA3 was measured on samples in a condition comparable to that used by Smart and Smith.¹⁹ However, the softening temperatures of the present specimens were determined from the hardness curves in Fig 2, where the greatest change of slope of these curves occurred. Therefore, the value listed in Table 3 could only be used for a qualitative comparison among each group.

From Table 3, it may be stated that the largest part of the phosphorus in specimen FA2 existed in the oxidized form, whereas that in specimen FA1

was most likely in solid solution with copper. The higher recrystallization temperature of FA1 and the lower value of FA2 also bear out this fact. It has been pointed out that recrystallization textures are subject to considerable variation because of alloying elements in solution. Furthermore, elements which conferred the greatest solution and strain-hardening on copper have shown the most complicated annealing texture.¹¹ It appears, therefore, certain complications will be introduced, in that the amount of phosphorus obtained by chemical analysis may not be used as a guide to specify the influence on the textures. The development of annealed texture for specimen FA1 may therefore be considered as following a different mechanism than that of specimen FA2 because of the different condition of phosphorus in each. In the case of H.C. copper, it was found that a well developed deformation texture—up to 80 to 95 pct reduction—was required before recrystallization would produce the cubic texture. For reductions of 50 to 80 pct, the texture existing in the annealed condition resembled that in the rolling condition.⁶ Referring to the rolling texture of specimen FA1, the greater spread of the major intensity of (111) distribution can be best ascribed to the presence of the minor texture (110)[001], which was found to be one of the intermediate orientations in cold-rolled copper.^{3,20} Thus it may be suggested that the absence of cubic texture in specimen FA1, probably due to the strain-hardening effect of the phosphorus in solid-solution, is analogous to that of H.C. copper deformed below 80 pct reduction. The random orientation at lower temperature and the development of a mixed (112)[111] and (110)[001] texture at 1600°F may also be attributed to the interference of phosphorus with the recrystallization mechanism.

The recrystallization texture of specimen FA2 annealed at lower temperature exhibited the same characteristics as specimens FA3, FA4 and FA5, that is, a strong cubic texture superimposed on a mixed deformation texture. However, when the annealing temperature was sufficiently high, above 1400°F, the cubic texture diminished in intensity and there was a great increase in grain size. The development of the large grains has been reported by Dahl and Pawlek¹⁰ for electrolytic copper of 100 pct cubic

texture annealed at high temperatures. They stated that the texture could be described as (120)[100]. The large grains have also been observed in annealed copper by Cook and Richards²¹ and Baldwin⁸ to possess a texture of (110)[112]. It was also found by Baldwin⁸ that the orientation of the huge grains growing out of a 100 pct cubic texture for lake and electrolytic copper can be best described as: (113) in the rolling plane and between [110],

[301] and $[2\bar{1}1]$ in the rolling direction. It might be suggested that the cubic orientation would be unfavorable under the process of grain growth, or in other words, it is less stable in large grains than other orientations described above. It appears, therefore, that the change of annealing texture as well as earing position in specimen FA2 at 1600°F could be considered to be a result of the absorption of grains of the cubic orientation during the grain growth leaving the other orientations predominant.

Summary

1. The cold-rolled texture of different types of copper strip was found to be less sensitive to the presence of phosphorus or other impurities than the recrystallization one. The ideal orientations of rolling texture may be described as the usual type, (110)[112] + (112)[111], but greater spread of the first intensity of (111) poles in phosphorized copper FA1, (0.013 pct P), may be considered as due to the presence of the minor texture (110)[001].

2. The recrystallization textures of phosphorized copper containing 0.013 pct P exhibited a rather random pattern for annealing at lower temperature, while at high temperature there was produced a texture of mixed orientations (112)[111] and (110)[001]. There was no appreciable change of earing position throughout the whole range of anneal.

3. The texture of phosphorized copper FA2 (0.007 pct P), oxygen-free high-conductivity copper FA3, electrolytic copper FA4 and fire-refined copper FA5, annealed at 900°F was found to be a strong (001)[100] texture superimposed on the retained deformation textures (124)[533], (110)[112] and (112)[111]. These minor orientations usually diminished in their intensities with an increase of final annealing temperature, while, in turn, a single cubic texture was approached in specimens of oxygen-free high-conductivity copper FA3, electrolytic copper FA4 and fire-refined copper FA5. For phosphorized copper containing 0.007 pct P, FA2, annealed at 1600°F, a texture of a mixture of orientations (113)[211], (110)[112] and (100)[001] was found, while the earing position in drawn cups changed from a pure copper type at 0° and 90° to 45° to the rolling direction.

4. In studying the data of electrical conductivity and softening tempera-

FIG 8—(111) Pole figures for cold-rolled copper strips annealed at 1600°F, for one hour.

tures of two types of phosphorized copper, it was suggested that the presence of phosphorus in coppers FA1 (0.013 pct P) and FA2 (0.007 pct P) would be in different conditions. Most of the phosphorus in FA1 may be considered as existing in solid solution with copper; thus the great influences on electrical conductivity, recrystallization temperature as well as textures and earing behavior would result. In specimen FA2, it appeared that most of the phosphorus probably existed in the oxidized form, which had less effect on the texture and earing behavior. However, the change of texture and position of ears at high temperature may be rationalized as the same function of development of various textures in the huge grains where the cubically aligned grains may be less stable than the others.

5. In regard to the earing behavior of these copper strips, it may be stated that the type and degree of preferred orientation are the most significant factors controlling the height and position of ears. An increase in grain size will usually have a tendency toward a preferred orientation, which in turn produces higher ears. The absence of ears in drawn cups may or may not

indicate the absence of preferred orientation, but may be due to the presence of orientations which counteract one another with respect to the earing behavior.

Acknowledgment

The author wishes to acknowledge the advice and suggestions of Dr. D. K. Crampton and Dr. H. L. Burghoff, and the assistance of Mr. J. Cooper, Jr. and other members of the Research Department of the Chase Brass and Copper Co. in the work reported here. Thanks are also due to Professor W. R. Hibbard, Jr., of Yale University for helpful criticism.

Use of Electrical Resistance Measurements to Determine the Solidus of the Lead-tin System

RALPH HULTGREN,* Member AIME, and STANLEY A. LEVER†

THE solidus is usually the least satisfactorily determined portion of a phase diagram. Cooling curves, which succeed well with the liquidus, show the solidus inaccurately or not at all because of segregation which occurs during freezing. Heating curves of carefully homogenized alloys might be expected to indicate accurately the solidus, but they are seldom used.

Dynamic methods involving heating or cooling are never completely satisfactory because of uncertainty as to whether equilibrium is attained. A static method in which the specimen may be allowed hours, days, or even weeks to attain equilibrium is to be preferred. In a static method a solid solution, for example, is first made thoroughly homogeneous, then heated to successively higher temperatures. After sufficient time at each temperature to assure equilibrium, some property is measured which should alter strikingly when melting begins. Microscopic examination can be used to detect the beginning of melting, but the method is tedious since the specimen must be quenched, sectioned, polished, and etched before each examination.

Of all the physical properties which change on melting, electrical resistance is probably the most satisfactory to measure. The measurement may be made while the specimen is at temperature without damage to the specimen. It may be repeated indefinitely to ascertain when equilibrium has been achieved. Measurements may be made on a single specimen over the whole range of temperature. Most metals approximately double their resistance on melting. Since an accuracy of a few tenths of a percent is easy to achieve, the method is highly sensitive to the beginning of melting.

In spite of these advantages, which have been perceived for a long time,^{1,2} a reasonable search of the literature

has failed to reveal a single case in which the method has been satisfactorily applied in practice to the determination of solidus temperatures. The use of electrical resistance measurements appears to have been confined in practice to changes in the solid state.

In the work described in the following pages we have applied the electrical resistance method to the solidus of the lead-tin system. We have found the method to be convenient, reproducible, and highly sensitive. We chose the lead-tin system because it leads to few technical difficulties. Furthermore, a number of determinations of solidus have been made in this system by various methods and results could be checked against them. However, all published results are not in good agreement with one another, so this work should help in determining the solidus more precisely.

The Lead-tin Diagram

Because of its commercial importance, there have been numerous investigations of the lead-tin diagram. The results of the most recent work on the solidus are indicated in Fig 7, as well as the results of the present work. The works of Honda and Abe³ and of Stockdale⁴ agree fairly well with each other and with the present work.

San Francisco Meeting, February 1949.

TP 2500 E, January 1949. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before April 15, 1949. Manuscript received September 10, 1948.

Most of the material presented in this paper was abstracted from a thesis submitted by Stanley A. Lever in partial fulfillment of the requirements for the degree Master of Science in Engineering, University of California.

Jeffery's⁵ data indicate the solidus to be about 50°C lower.

Honda and Abe³ used differential thermal analysis on both heating and cooling cycles. Stockdale⁴ used the microscopic method and also differential heating curves. Stockdale's results were about 4° higher than those of Honda and Abe at low tin contents and lower at higher tin contents. These results also agree with those of Rosenhain and Tucker.⁶

Jeffery⁵ used electrical resistance measurements of the alloy as it was being heated or cooled. Apparently he did not attain equilibrium as his results are about 40°C lower than those of Stockdale⁴ or Honda and Abe.³

MATERIALS AND METHODS

The lead and tin used were of high purity. They were supplied by the American Smelting and Refining Co., who gave the following analyses:

Lead: silver, 0.0016 oz per ton; copper, 0.0008 pct; cadmium, 0.0007 pct; zinc, 0.0002 pct; arsenic, 0.0003 pct; antimony, 0.0002 pct; bismuth, 0.0005 pct; tin, 0.0001 pct; iron, 0.0020 pct; lead (by difference), 99.995 pct.

Tin: antimony, 0.037 pct; arsenic, 0.020 pct; bismuth, 0.004 pct; cadmium, trace; copper, 0.025 pct; iron, 0.004 pct; lead, 0.020 pct; nickel and cobalt, 0.005 pct; silver, 0.0005 pct; sulphur, 0.005 pct; tin (by difference), 99.88 pct.

One hundred grams of metal with the desired proportions of lead and tin was weighed out to the nearest one-tenth of a milligram. The mixture was placed in a silica crucible, covered with charcoal, and melted in a reducing atmosphere in a gas-fired furnace. The alloy was well stirred. Chemical analysis of two of the alloys checked closely with the weighed portions. The compositions of the remainder of the alloys were taken directly from the weighings, without chemical analysis.

FIG 1—Pyrex U-tube and electrical connections to Kelvin double bridge.

FIG 2—Electrical resistance vs. temperature, 5 pct tin alloy.

FIG 3—Electrical resistance vs. temperature, 10 pct tin alloy.

FIG 4—Electrical resistance vs. temperature, 15 pct tin alloy.

The pyrex glass tubing shown in Fig 1 was heated in a Lindberg cyclone furnace and held at a temperature of 400°C. A gas mixture consisting of 98 pct nitrogen and 2 pct hydrogen was passed through it for about one-half hour. The well stirred molten alloy was then poured into the tubing and allowed to remain for about one-half hour while electrical connections were being inserted.

The electric lead wires had been stripped of insulation, cleaned with nitric acid and finally washed with alcohol and dried. Stranded 14-ga copper wires were introduced into the outer arms of the tube, and stranded 18-ga copper wire into the inner arms. Fine (30 ga) iron-constantan thermocouple wires insulated with braided glass were introduced so that the hot junction was at point 1. The tube was then removed from the furnace and cooled rapidly in a stream of cool air in order to minimize segregation on

freezing. Before measurements were taken, the alloy in the tube was given a homogenizing anneal of about two days at a temperature about 50°C below Stockdale's value of the solidus.

For the measurements of electrical resistance the tube was heated in a metal bath composed of lead, tin, and bismuth and having a melting point of about 170°C. The temperature of the bath was held constant to $\pm 1^\circ\text{C}$.

Resistance measurements were made with a Leeds and Northrup Kelvin Double Bridge Ohmmeter. This bridge is more suitable than a Wheatstone bridge for low values of resistance, since the effect of contact resistance is very small. A diagram of electrical connections is shown in Fig 1. External leads are shown as dotted lines. The external electrical leads were approximately 2 ft long. The leads to the connections C_1 and C_2 each consisted of two 14-ga stranded copper wires in parallel, those to P_1 and P_2 of two

18-ga stranded copper wires in parallel. The readings of resistance were estimated to be accurate to about 0.000005 ohms, which is of the order of 0.2 pct.

In making the measurements it was necessary to pass a current of about 7 amp through the metal for a period of less than 15 sec. It can be shown that this is capable of raising the temperature of the alloy less than 2°C . Measurements with the thermocouple imbedded in the alloy indicated the actual temperature rise during a measurement was less than 0.2°C .

Temperature measurements of the alloy were made on a precision potentiometer using the very fine (30 ga) iron-constantan thermocouple mentioned above. Readings are estimated to be accurate to about 0.5°C .

During the homogenizing anneal, electrical resistance measurements were taken from time to time. It was usually observed that the values obtained changed slowly for about two days,

FIG 5—Electrical resistance vs. temperature, 19 pct tin alloy.

FIG 6—Electrical resistance vs. temperature, 24 pct tin alloy.

FIG 7—Solidus and liquidus of lead-tin system.

then settled to a constant value. This was taken to indicate that the alloy was homogeneous and the resistance was recorded.

The temperature of the bath was then raised a few degrees and held there until the resistance readings again became constant. Usually five to six hours was allowed for this, although in many cases the alloy remained at temperature overnight. When the resistance did not change for one hour, it was assumed that equilibrium was attained. This process was continued through the solidus and liquidus of the alloy. Temperature intervals in critical regions amounted to only two or three degrees.

Results and Conclusions

The resistance vs. temperature curves obtained are shown in Fig 2-6. As can be seen, these curves are accurate straight lines for the alloy in the solid state. As the alloy begins to melt at the solidus, however, there is a sharp increase in slope of the curve. The experimental points follow the curves accurately, so that the solidus

is determined precisely in each case. There is a similar sharp change in slope at the liquidus.

In the alloys containing 19 and 24 pct tin (Fig 5 and 6), melting begins at 183°C with a small discontinuity in the curve. This is due to the melting of a small amount of the eutectic.

In the alloy containing 24 pct tin, there is also a small but sharp discontinuity at 161°C. We attribute this to a change in the tin-rich phase, which is present in appreciable amount only in this alloy. Other observers⁷ have noted discontinuities in volume and electrical resistance in tin at this temperature although this result is disputed by some. Mason and Pellissier⁷ report that the high temperature X ray camera shows there is no change in phase of tin at elevated temperatures. To add to the confusion, observers have reported discontinuities at a number of other temperatures. We are unable to account for our result.

The solidus and liquidus points determined in this investigation are plotted in Fig 7, along with the results

of other investigators. The liquidus determinations of all workers agree excellently. Except for the work of Jeffery,⁵ the solidus points fall rather closely together. However, our results are somewhat higher than those of Honda and Abe³ at all compositions, and higher than those of Stockdale⁴ at low tin contents. The fact that residual segregation would cause results to be too low rather than too high indicates that our results are to be preferred.

We believe this work has shown that electrical resistance measurement is a convenient method of determining the solidus (and the liquidus) curve with high precision.

Controlled Grain Growth Applied to the Problem of Grain Boundary Energy Measurements

C. G. DUNN,* Member AIME

THE measurement of interfacial tensions or grain boundary energies in metals is an important metallurgical problem, especially since it bears on growth and nucleation processes. Statistical methods of measuring equilibrium grain boundary angles, which relate interfacial tensions, have been used by some investigators^{1,2} but more direct methods would be preferred.

A direct way, based on a simple extension of a successful method of growing single crystals of silicon ferrite to predetermined orientations in flat specimens,³ is to produce three-grain specimens in such a way that the equilibrium common grain boundary will be perpendicular to the surface of the specimen. The angles to be measured then appear as the grain boundary angles in the surface of the specimen.

The method of producing a single crystal specimen with a predetermined orientation is basically the same as that employed by Yoshida and Fujiwara⁴ in their work on aluminum wires. The specimen, prior to any single crystal transformation, must have a matrix which will support the growth of a crystal of the desired orientation. Growth may occur through exaggerated grain growth or, if the matrix is strained a critical amount, by normal recrystallization. In either case the matrix must have stability at the temperature used to effect the transformation, this stability appearing as a long induction period for exaggerated grain growth or for the formation of recrystallization nuclei. Additional control is gained by using a high temperature gradient through which the specimen is moved at a suitable rate. To obtain the desired orientation, the specimen is fed a short way into the furnace producing one or more crystals in the hot end. After the specimen is removed from the furnace, the orientation of a crystal is determined, so that this crystal may be reoriented by properly deforming a narrow piece of the matrix between the end crystal and the rest of the specimen. This part of the specimen in the case of silicon ferrite is preferably

FIG 1—Photograph showing fine grained specimen with reoriented seed crystal in the form of small flag on end of the narrow twisted part of the specimen. Natural size.

FIG 2—Photograph showing specimen composed of three grains each having a {110} plane in the plane of the specimen. Sample ready to be annealed. $\times 2$.

held at red heat during the reorienting process. Fig 1 shows a specimen which is ready to be transformed into a single crystal through growth of a reoriented "seed" crystal.

When the method just described is applied to the production of a three-grain specimen two crystals are grown first side by side in one end, the specimen is then reversed and the third grain grown from the opposite end. A suitable group of grains each of different orientation is one where all three grains have the same crystallographic plane in the plane of the specimen.[†]

Fig 2 shows a photograph of a three-grain group prepared as described. The notches are introduced in the open

ends of the grain boundaries to anchor them during the final annealing operations which ultimately should bring the grain boundaries to the lowest energy configuration.

Two-grain groups with different crystallographic planes in the plane of the specimen can be similarly prepared and treated. If the two grains have different surface (gas to metal) energies per unit area, the equilibrium condition leads to a curved grain boundary.*

* This feature of the problem was pointed out by J. C. Fisher.

Development of the Modern Zinc Retort in the United States

H. R. PAGE,* and A. E. LEE, JR.*

From the inception of zinc retorting on a commercial scale in the United States in 1890,¹ the retort employed has undergone wide variations in its composition and manufacture, facilitating in part equally remarkable improvements in furnace capacities. The early day hand made clay retort was charged with carbonates or silicates or with coarse dead roasted concentrates mixed with a large proportion of charge fuel resulting in a relatively low zinc burden and fired 24 hr in direct coal fired furnaces. Its modern counterpart is fabricated in hydraulic presses from clay mixtures containing sizeable amounts of either silicon carbide or silica flour, charged with sintered flotation concentrates to more than three times the early day zinc burden and fired 24 to 48 hr in gas fired furnaces.

This paper does not attempt to describe in detail the early day clay retort practice as it is well outlined in treatises by Ingalls,² Lodin,³ Liebig,⁴ Hofman⁵ and others. A brief review of clay retort practice is presented together with a description of the major developments since 1912.

Clay Retorts

The Belgian type retort, both in the circular and elliptical forms, has been used almost exclusively. Typical dimensions of press made clay retorts around 1910 are shown in Table 1. Variations in these dimensions were used at different plants according to local conditions to a maximum inside diameter of 9 in. and inside length of 54 in. However, the effective heat penetration in a 24 hr firing cycle and the tendency of the retort to bend limited the retort size. Use of the elliptical vessel was an attempt to present a stronger cross-section resisting the tendency to bend and to increase the burden without increasing the depth of heat penetration.

Table 1 . . . Typical Dimensions of Press Made Clay Retorts around 1910

| | Circular, In. | Elliptical, In. |
|----------------------|------------------|--------------------|
| Inside diameter..... | 8 | 7.5 × 10.5 |
| Inside length..... | 50 | 50 |
| Wall thickness..... | 1½ | 1½ |
| Butt thickness..... | 2½ | 2½ |

One exception to the 48-54 in. length was the 60 in. retort used as early as 1905 at Palmerton by means of supporting the last 12 in. at the butt end with a specially designed furnace back-wall. This backwall construction with the 60 in. retort had been developed and used at Bethlehem by G. G. Conners and A. B. DeSaules. An attempt was made at Blende, Colo. to use even larger retorts of the Rhenish type based on European practice and requiring much higher furnace temperatures. Satisfactory plastic clays capable of withstanding these temperatures were not available, and the plant never operated successfully.

PREPARATION OF BATCH

Composition of the clay retort by weight was 40 to 50 pct raw clay and the balance "grog." Generally speaking the mix consisted of 7 parts plastic clay to 9 parts grog by volume. Principal source of the clay used was the Cheltenham vein—sometimes referred to as "St. Louis city clay." A typical analysis was Al₂O₃-31.0 pct, SiO₂-50.0 pct, Fe₂O₃-2.5 pct, MgO-0.3 pct, CaO-1.5 pct and loss on ignition 14.0 pct.

At the smelter the clay was weathered whenever possible and then crushed to 0.08 in. or finer. Grog consisted of calcined adobies, cleaned retort scrap and cleaned refuse fire brick such as old furnace brick, blast furnace linings, and others. Saggars from ceramic plants and calcined flint clay were later used. The grog materials were ground to 0.12 in. or finer. Occasionally coke dust up to 10 pct of the mix was substituted for a part of the grog following European practice.²

Particle size of the grog has a major influence on the retort properties—the larger the grain, the better can the retort withstand thermal shocks, resist bending at furnace temperatures and resist corrosion from slag; the smaller the grain, the lower the loss of zinc vapor through the retort walls. Grog forms the skeleton of the retort, and the clay shrinks around its grains to act as a binder. In the drying process, the grog has a stabilizing effect on the drying rate, decreasing shrinkage and giving up previously absorbed water to the surrounding clay to minimize the danger of cracking or checking.²

Grog and clay were mixed through a horizontal pug mill with 10 to 20 pct water added, depending on whether the retort was to be formed by hand or mechanically, more water being required for the hand process. The batch or "mud" extruded from the pug mill was cut in convenient lengths for handling, stacked in piles or in special rooms, covered with wet burlap and allowed to "rot" or age from 1 to 8 weeks to increase plasticity.

HAND MOLDING

If the retort was to be molded by hand, the mud was repugged after the rotting period and given to the molders. Their molds consisted of 3 sheet iron or wood cylinders, each one third the retort length and defining the outer shape of the retort. Beginning with the bottom section, mud was placed in the form and tamped with a rammer

San Francisco Meeting, February 1949.

* Assistant Superintendent and Metallurgist, respectively, Blackwell Zinc Co., Blackwell, Okla.
¹ References are at the end of the paper.

shaped to correspond with the retort interior. This formed a cup from which the retort walls were built up by winding a sort of rope of mud around the interior periphery of the mold. Each addition was tamped into place and the desired interior contour maintained by smoothing with a semicircular tool. Adjoining edges of the mud were roughened to secure a good bond. This process was continued, adding the remaining mold cylinders as required, until the retort was completed. After standing 48 hr the mold was removed and the retort air dried 1 to 3 weeks before being placed in the hot dry rooms.⁵

AUGUR MACHINE

Hand molding was superseded by use of the augur machine in forming retorts. The method of treating the mud between the rotting rooms and the machine varied at different plants. A few plants fed the mud directly to the machine; others repugged it first either in the mixing pug mill or in a larger more powerful mill extruding a 12 to 14 in. mud cylinder. The augur machine consisted essentially of a circular hopper to receive the mud, a series of blades on a central shaft to force the mud downward and a reduced section die and core representing the cross-section of the retort. The machine was arranged to discharge the retort downward in the form of a pipe which was received on a counterbalanced table passing through a temporary wooden mold. When the proper length cylinder had issued from the machine, the augur was stopped and the cylinder cut off, leaving it encased in the wooden mold. A ball of mud was thrown into the cylinder and tamped into place to form the retort butt. As in the case of the hand made vessel, the mold was left on for 48 hr, and the retort dried in the same manner.⁵

HYDRAULIC PRESS

Following the augur machine, a hydraulic press invented by a Belgian, E. Dor, and manufactured by C. Mehler, Aix-la-Chapelle, came into general use. Retorts made in the press, while more expensive than augur units, were denser and stronger. As a result, losses of zinc by absorption and penetration were reduced, a longer life and greater resistance to bending and corrosion were gained, and the charge could be forced longer at high temperatures to effect better zinc recoveries.² A further refinement in the Mehler

press was effected in the unit made by C. A. Wettengel which formed retorts at higher pressures, was more durably constructed and incorporated a number of labor saving devices.⁵

For use in the press the mud had to be formed into ballots about 16 in. long, 14 in. in diam and weighing 200 lb. Initially this was accomplished by feeding mud from the rotting rooms to a hammering or "Schlag" machine. In time the Schlag machine was replaced by a powerful pug mill extruding a 14 in. diam ballot to be cut off in the proper lengths.

The ballot is placed in the receiver of the press and the die block and cover plate of the press closed and locked. Two rams, one a center punch corresponding to the retort interior and the other an annular ring between the receiver walls and the center punch, rise to compress the ballot. The center ram continues upward to a predetermined distance from the cover plate to form the retort butt while the ring retreats downward in corresponding displacement. After the desired pressure has been reached, the cover plate is swung open and the retort extruded upward between the die block and center ram by pressure from the ring ram. As the retort moves upward, it is guided by a sliding pipe framework with a plate fitting over the retort butt. After trimming to the desired length, the retort is placed in the drying room, no molds being required.

DRYING AND ANNEALING

Freshly made retorts were placed in rooms at atmospheric temperatures for 1 to 3 weeks. Then they were moved to hot rooms at 100 to 140°F for a period of 4 weeks to 6 months to be withdrawn as required by the furnaces. Some plants used a series of 2 or 3 hot rooms each at progressively higher temperatures. Prior to being used in the furnace, the dried retorts were sealed in small kilns and over a period of 15 to 20 hr gradually heated to 1500–1800°F. They were removed at this temperature and placed immediately in the furnace.

PERFORMANCE

The life and performance of clay retorts were materially improved by use of the hydraulic press. Life of a press made clay retort in a 24 hr furnace often averaged as high as 30 days with low iron ores such as coarse Joplin or Willemite. The M & H plant at La

Salle is said to have had an outstanding record in this respect, achieving an average of 90 days with small diameter retorts and low burden of Joplin ore in the early 1900's. With western ores of higher iron content, however, the life was as low as 12 to 14 days in some cases. There was a sizeable loss of zinc vapor by absorption in the walls of the retort (7–9 pct of the retort weight) and by penetration through the walls into the laboratory of the furnace (estimated as high as 2 pct of the zinc in the charge by some operators). Retort failures were caused by excessive bending, build up of loam outside and "rock oxide" inside the retort mouth, cracking from thermal and physical shock, slag boring and corrosion. Among various attempted solutions to these difficulties were glazing² the exterior and/or interior of the retort to reduce vapor absorption and penetration, coating the interior with a noncorrosive basic lining² to resist slag corrosion from iron ores, making the retort bottom thicker than the other walls to give added strength and reduce boring losses, and making the retort in layers⁵ of different materials—the interior to resist corrosion and the exterior to form the body of the retort.

Silicon Carbide Retorts

About 1912 the New Jersey Zinc Co. began experimenting with the use of silicon carbide in the retort mix in an effort to improve the life of the clay vessel. Although the higher cost of the retort was recognized at the outset, there were in addition to longer life and other potential advantages several attractive features at the Palmerton plant. These were the possibility of reducing the amount of St. Louis clay on which the freight charge was high, the nearby commercial electric furnace production of silicon carbide together with the producer's desire to find new uses, and the smelter's large scale use of Willemite ore.

The first retorts were cast units of very high silicon carbide content and failed as a result of thermal shock after a short time. Then followed a period of experimentation using carbide crushed and sized to the recommendation of the Carborundum Co., mixed with plastic clay, and processed in the conventional manner. About 1913 a batch consisting of 88 pct silicon carbide and 12 pct plastic clay by weight was prepared by hand mixing and working over a period of several weeks by Jake

Miller, a skillful potteryman. Ballots were prepared in a Schlag machine and passed through a Mehler press making 2 retorts. After drying and burning in the conventional manner, they were placed together in the middle of the second row of a 4 high Siemens regenerative furnace fired with producer gas made from anthracite coal. One of these retorts lasted 10 months and the other 355 days. A mix of 70 pct silicon carbide and 30 pct plastic clay was finally adopted as the composition which could best be worked with the then existing pottery equipment. Some years later this was changed to 65-35 pct. Under the conditions at Palmer-ton, the method of crushing the silicon carbide was found to be most important, and pan mill ground grain to produce a size distribution approximat-ing Fuller's curve of minimum voids gave the best results.

The advantages realized at Palmer-ton in replacing clay retorts with car-bide have combined to effect savings beyond the additional retort cost. These are: longer life—an average well over 100 days over the years—a more rigid piece of refractory permitting the use of a 5 ft retort without extra butt support, improved zinc recovery, smelt-ing time saved in changing fewer retorts, better heat transfer with conse-quent fuel saving and better control of furnace.

There is a definite reaction between the silicon carbide and basic con-stituents of the charge, including zinc oxide, tending to decompose the car-bide. The practice of salt additions in sintering is prohibited, and its use mixed with the charge is limited to a maximum of 0.25 pct because of the alkali reaction. Basic and alkali bearing dust carried in the producer gas used in firing attacks the exterior of the retort similarly. The highly acidic nature of the residue from the Wil-lemite ore-anthracite coal charge un-doubtedly contributes to the successful results at Palmerton.

Manufacture of silicon carbide re-torts for use with sintered zinc sulphide charges has been described by E. J. Bruderlin⁶ at the Amarillo plant of the American Smelting and Refining Co. Current retort size is 9¼ in. inside diameter, 62 in. inside length, 1½ in. wall, 2½ in. butt, weight burned 224 lb. Amarillo uses 2 classes of retorts—the No. 1 class made with clean, freshly produced silicon carbide and the No. 2 class made with about half new mate-rial and half reclaimed carbide. The

average life in calendar days of these retorts for the period 1940 to 1947 in-clusive was 228.6 days for the No. 1 retort and 123.1 for the No. 2. During this period 24, 28, 32, 36 and 48 hr cycles were used.

Silica Retorts

After the silicon carbide retort had been established successfully at Pal-merton, several smelters experimented with the use of carbide in their retort mixes. However, the high cost, close process control required and relatively difficult furnace working conditions were prohibitive in most instances, and other methods of improving the clay vessel were sought.

During a visit to the Hillsboro plant of the American Zinc, Lead and Smelt-ing Co. about 1915, a German engineer named Salzberg mentioned that Ger-man retort clays contained relatively high silica. In 1919 while experimenting with a wide variety of refractory materials mixed with the regular clay-grog mix in an effort to produce a longer retort which would resist bend-ing, the Rose Lake smelter of the same company tested silica additions from 5 pct through 35 pct by volume of the mix. As a result of this work, the high silica retort mix became regular prac-tice at Rose Lake in 1920, although the volume of silica was not standardized at 25 pct until 1929.

W. F. Rossman⁷ of the American Zinc, Lead and Smelting Co. patented the high silica retort in 1922, specifying proportions by volume of 50 pct plastic clay, 25 pct grog and 25 pct silica flour of minus 140 mesh. Manufacture and performance of this retort at Rose Lake were described by G. L. Spencer, Jr.,⁸ in 1931. The first license under the patent was granted May 1, 1928 to the Hegeler Zinc Co., and within a few years the silica vessel was adopted universally by the other smelters not using silicon carbide.

From the information available, the 25 pct proportion of silica has been followed by the industry, although variations in the volumes of clay and grog have been made. For example, Dumas uses a mix of 45 pct plastic clay, 30 pct grog and 25 pct silica flour. The 5 pct additional grog is intended to further stiffen the retort, but no data are available to prove or disprove the benefits.

A further improvement in the prac-tice of manufacturing both carbide and silica retorts was the use of the de-

airing pug mill. This equipment was developed at the Donora Zinc Works in 1940 and has been described by M. M. Neale.⁹ Greater density and strength of the retort wall are the principal advantages. Another recent innovation is controlled humidity or "quick" dry-ing of retorts, introduced at Donora¹⁰ on a commercial scale in 1947. Un-doubtedly this process removes me-chanical moisture much more rapidly and uniformly than is done during the first 15-45 days in the conventional drying room. However, the value of long aging in addition to drying is considered by some smelters to be of great importance to long retort life, and some believe that aging of quick dried retorts will materially improve them.

As an example of current manufac-ture of silica retorts, the practice of the Blackwell Zinc Co. is described. The retort is of circular cross-section and has the following dimensions burned: inside diameter 9¼ in., in-side length 62 in., wall 1½ in., butt 2¼ in., weight 171 lb.

MATERIALS

Materials used in fabricating the retort and their proportions by volume are 50 pct plastic clay, 25 pct grog and 25 pct silica flour. Wet weights per cu ft and average moisture content of the crushed materials as used are: clay, 78 lb per cu ft, 7.0 pct moisture; grog, 80 and 1.0 pct; silica flour, 68 and 0.5 pct. Missouri clay from the area about 100 miles northwest of St. Louis is used and has approximately the composition shown in Table 2. After weathering 6 to 12 months whenever possible, the clay is sized to minus 0.095 in. Grog is purchased de-aired setter slab mate-rial which has been used in making and burning fire brick. A typical analysis is given in Table 2. Grog is sized to minus 0.120 in. Silica flour is of high quality, assaying approximately 99.5 pct SiO₂, and is in the form of a fine flour, 95 pct through a 150 mesh sieve and 50 pct through 200 mesh.

Table 2 . . . Analysis of Clay and Grog Used in Blackwell Retorts

| | Clay, Pct | Grog, Pct |
|--------------------------------|-----------|-----------|
| Al ₂ O ₃ | 30.5 | 38.9 |
| SiO ₂ | 58.0 | 56.0 |
| Fe ₂ O ₃ | 1.0 | 4.2 |
| MgO | 0.1 | 0.14 |
| CaO | 0.2 | 0.35 |
| S | 0.2 | 0.12 |
| Loss on ignition | 9.8 | 0.0 |

FORMING RETORTS

Desired quantities of clay, grog and silica are bucketed into a horizontal pug mill from adjacent storage bins. Sufficient water, usually 12.5 to 13.0 pct in the mix, is added to produce the desired stiffness. The mud is extruded through a round cornered $7\frac{3}{4} \times 10\frac{3}{4}$ in. opening from the mill, cut and stacked nearby. When approximately 23 tons (enough for 235 retorts) has been made, the feed of raw materials is stopped and the entire batch immediately repugged. It is recut and stacked in rotting rooms for 5 to 6 days. After the rotting period, the mud is fed into a Bonnot de-airing pug mill where it is repugged, shredded, de-aired under a vacuum of 25–27 in. of mercury, and compressed into an ejecting cylinder 15 in. in diam. The ballots are cut off in 17 in. lengths and made into retorts in a Mehler press. The butt is formed with a pressure on the mud of 1050–1100 psi and the walls extruded at 300–350 psi. After trimming to proper length, the retorts are wheeled individually on rubber tired trucks to the drying rooms.

DRYING

Drying rooms have brick walls and a gently sloping frame roof. The floor is made of wood 2×4 's laid flat and spaced $\frac{1}{4}$ in. apart over the floor joists. To a height of 6 ft from the floor, a rough wood wainscoting separates the retorts from the brick walls by a 4 in. airspace. In the roof are constructed 2 ventilators with the outside openings shielded from possible entry of rain and containing dampers for varying the openings. Steam pipes are laid 6 in. below the floor and at the ceiling to effect drying. The average room holds about 1500 retorts.

Prior to using a room for drying, all steam is shut off, the ventilators are closed, and the walls and floor wet down. The retorts are carefully placed in rows beginning against the farthest wall from the door. Each retort is put as close as possible to its neighbors with each row interlocking the preceding row. At the end of each production shift, the exposed row is covered with damp burlap and the door closed. When the room is filled, boards are placed across the doorway to a height of 6 ft, the retorts in the doorway covered with burlap and the door closed.

Depending on outside conditions, the

temperature in the room will average 80°F when filling is completed. Daily checking of the room is required, and its temperature at a regular time each day is recorded on a chart on the door. On the fifteenth day after closing, the ventilators are opened and steam is cracked on the floor coils. Steam additions are carefully controlled so that the temperature rises only 1 or 2° each day. When possible, all drying is effected with the floor coils only. However, after 30 days from start of heating, steam may be turned in the ceiling coils if necessary to maintain the temperature increase until 135°F is reached. Occasionally in cold weather it is necessary to use the top coils to prevent condensation drips from the ceiling.

The room is held at 130–135°F until opened for furnace use. Retorts are in the rooms 90 to 120 days. Loss in drying based on retorts used in the furnaces is quite low as evidenced by the following: 1945—0.12 pct, 1946—0.16 pct, 1947—0.11 pct.

PREHEATING

On the day preceding the prescribed furnace maneuver, the required number of retorts is taken from the oldest drying room and placed in conventional down draft gas-fired kilns. Doors are sealed and the kilns fired at 3 in the afternoon in anticipation of use the following morning between 6 and 9. Heating is gradual to a maximum of 1600–1800°F during the latter part of the period. When retorts are to be withdrawn, the gas is shut off and the doors opened. The retort must be placed immediately in the furnace when taken from the kiln as it is very sensitive to temperature change. During any pause in the removal of retorts over a few minutes duration, the kiln door is closed and the gas reapplied.

Retort loss at the kilns is 4 pct based on retorts used in the furnaces. 1 pct of this is due to errors in firing—primarily spalling from too rapid heating. 3 pct represents breakage from faulty handling on removal from the kiln. All retorts lost at the kilns are collected and returned to the pottery for use as grog. Retorts lost in drying are hard burned in a kiln and used in the same way.

PERFORMANCE

Performance of the silica retort at Blackwell for the period 1943 through

August, 1948, is shown in Table 3. Ores used during this time were about one third low iron sulphide flotation concentrates of about 2.5 pct Fe in the green ore and two thirds containing about 7.0 pct Fe.

Table 3 . . . Performance of Silica Retort at Blackwell

* Furnace cycle 24 hr before June 1944 and 93 pct at 48 hr since.

Conclusion

The history of the horizontal zinc retort in the United States records a continual effort to enlarge the retort. The two most significant developments in this respect were the use of the hydraulic press in forming retorts and the use of silicon carbide and silica flour mixes. The 62–64 in. inside length employed today is not the limit at which the modern retort can effectively resist bending but is, rather, the supposed practical limit of effective manual charging. Extending the furnace cycle beyond 24 hr has permitted on a practical scale increasing diameter. However, even with the 48 hr cycle the maximum distance for heat penetration appears to be limited depending on the slagging characteristics of the ores charged. Longer life and improved wall density of modern retorts have made possible better zinc recoveries.

While the advantages of both the silicon carbide and silica retorts are easily discernible over the clay vessel, it is difficult to make any such distinction between the former. In the United States only the two primary zinc smelters previously mentioned use carbide retorts, and the balance use silica. In cost the carbide retort is 4 to 6 times as expensive, but correspondingly, its life is 3 to 4 times as long in terms of charge cycles dependent on the composition of ores used and character of the firing fuel.

Heat transfer within the furnace is much more effectively accomplished with the carbide than the silica. Carbide retorts can be and are fired to higher temperatures than silica retorts, resulting in lower zinc in the residue but greater demands on furnace linings. Special refractories are sometimes resorted to where carbide retorts are used. Because of the longer life, more attention must be given to

chiseling out loam build up and "rock oxide." For the same reason, use of carbide retorts in Hegeler furnaces is impractical because of build up of fusible fly ash fastening retorts to the shelves. The use of salt in sintering and in preparing the charge is restricted. Residual sinter sulphur must be held to a low figure, preferably 0.2 pct or lower. The silica retort is subject to boring and corrosion by fusible iron slags but is considerably easier to cut out and replace in the furnace. Thermal shock below furnace temperatures is much more damaging to the silica, even the old clay retort being superior in this respect. Because of the better heat transfer, heavier retort weight and greater difficulty in cutting out retorts, the working conditions are said to be less satisfactory on a silicon carbide retort furnace. On the other hand, changing less retorts per cycle at least partially offsets this. Practical burdens per retort are about the same for both vessels. Other things being equal, the

longer life of carbide retorts should make possible higher recoveries of zinc. Choice of the retort is a matter depending on local conditions at the individual smelter.

Acknowledgment

The assistance of Mr. Francis P. Sinn of the American Metal Co. and Mr. Chester Skinner and the staff at Blackwell in preparing this paper is gratefully acknowledged. Thanks are extended to Mr. Henry Hardenbergh and Mr. L. S. Holstein of the New Jersey Zinc Co. for data on the early history of the silicon carbide retort and its use at Palmerton; to Mr. E. J. Bruderlin of the American Smelting and Refining Co. for data on the use of silicon carbide retorts at Amarillo; and to Mr. Robert Ammon and Mr. G. L. Spencer, Jr. of the American Zinc, Lead and Smelting Co. for the history of the silica flour retort.

The Effect of Strain-temperature History on the Flow and Fracture Characteristics of an Annealed Steel*

E. J. RIPLING† and G. SACHS,† Member AIME

Introduction

ALL ferrous alloys can be made brittle by straining at sufficiently low temperatures. However, the changes in mechanical properties for different ferrous materials with decreasing testing temperature do not appear to follow any universal law.

In particular, complex effects of testing temperature have been observed if cold worked steels were subjected to tensile tests at low temperatures.

EFFECTS OF PRETRAINING AT A TEMPERATURE ABOVE THE TESTING TEMPERATURE ON THE FRACTURE CHARACTERISTICS†

A considerable amount of data has been presented by a number of investigators on the fracture characteristics of various cold worked steels.¹ These data usually relate to a two-step procedure first used by Davidenkov,² consisting of stretching by tension to a certain strain or "prestraining" at room temperature and then completing the tensile test, or "testing" at the temperature of liquid air.

On the basis of data of this type made available to date, ferrous alloys can be classified into two groups with respect to their fracture characteristics observed on testing at a low temperature after prestraining at room temperature. Very complex phenomena have been observed for all annealed steels. On the other hand, some observations indicate that steels in certain other conditions represent a fundamentally simpler relation.

In considering the effect of prestraining at one temperature on the properties obtained at some lower temperature, it should be expected that any cold work reduces the ductility

retained in proportion to the magnitude of the cold work. However, the test data presented to date indicate that only heat treated (quenched and tempered) steels appear to conform to this expectation, according to the very limited test data in Fig 1, presented by McAdam, Geil and Mebs. This series of tests, Fig 1, shows that the retained ductility became smaller the larger the prestrain. However, this decrease is less than the amount of prestrain or, in other words, less than the decrease in ductility at the prestraining temperature.

These effects of prestraining are fundamentally identical with those observed by Bridgman³ when a steel was prestrained (in tension) under hydrostatic pressure and then subjected to a regular tension test. It appears, therefore, that the basic effect of prestraining under conditions which yield a higher ductility than the (subsequent)

testing procedure, consists of gradually increasing the total ductility of the metal from the initial low value of testing to the higher value of prestraining.

On the other hand, all annealed steels, if cold worked by tension at room temperature and then tested at a lower temperature, provided that some ductility is retained, showed a far more complex behavior than that discussed above. This relationship is exemplified by Fig 2, for three pearlitic steels.^{4,5} These particular steels were selected because of the various shapes of their ductility-prestrain curves. All three steels, and any other investigated so far, suffered a rapid decrease in retained (and consequently also in total) ductility when subjected to small prestrains. Then, after exceeding a certain prestrain it was generally observed that the ductility recovered.*

This rather complex behavior of annealed steels may be tentatively correlated with the presence of stretcher strains at small prestrains. Heat treated steels do not exhibit stretcher strains. This fact might possibly explain their simpler prestrain-retained ductility relationship.

The destructive effect of these stretcher strains may possibly be associated with the presence of triaxiality, which may occur in any highly non-uniform stress and strain state (and which is retained as residual stress after unloading). Even a small degree of triaxiality may then cause a reduction in ductility, or even embrittlement at a sufficiently low testing temperature.

The discussion presented above deals with the effects of cold working at a high temperature on the fracturing

† Research Laboratory for Mechanical Metallurgy, Case Institute of Technology, Cleveland, Ohio.

‡ In most investigations in which the effect of some variable or variables on the fracturing characteristics is to be determined, it has been found that the ductility generally responds to the variables more simply and accurately than the fracture stress. Consequently, in this paper the main emphasis will be placed on ductility changes.

1 References are at the end of the paper.

* This damaging effect of small tensile strains on the low temperature properties of annealed steels is further revealed by some tests made by Davidenkov and Sakharov² on a 0.20 to 0.25 pct carbon steel. The transition temperature of this steel was found to go through a maximum at small prestrains, as shown in Fig 3.

FIG 1—Effect of prestraining in tension at room temperature on the ductility at a low temperature (-190°C) obtained on a heat treated steel (McAdam, Geil, and Mebs).

characteristics at a lower temperature. Apparently, the reverse case, that is, prestraining at a low temperature and testing at a higher temperature to failure, has not yet attracted any attention.

EFFECT OF PRESTRAINING AT ONE TEMPERATURE ON THE FLOW CHARACTERISTICS AT A HIGHER AND A LOWER TESTING TEMPERATURE

The effect of two-step, cold work treatments has also been investigated on another metal characteristic, that is, strain hardening, as represented by the general shape of the stress-strain curve. The very limited data presented by Hollomon⁶ obtained on a 1020 steel have been evaluated by him to prove that the temperature of prestraining has no effect on the strain hardening observed at a given temperature, Fig 4. In other words, the state of strain hardening is independent of the straining temperature, as long as the temperature is sufficiently low to prevent diffusion.

According to some data by Orowan,⁷ however, obtained on copper which was strained in steps at room temperature and at the temperature of liquid

nitrogen, Fig 5, the stress at any particular strain is very greatly affected by the temperature at which the strain was made. Furthermore, in some more recent tests, Dorn, Goldberg and Tietz⁸ prestrained 2SO aluminum at various temperatures and then tested it at both a higher and a lower temperature than the prestraining temperature. Their results were in agreement with those of Orowan in that the flow stress at any particular strain depended greatly on the strain history. Furthermore, they found that prestraining at a high temperature had a greater effect on the flow stress at the low temperature than the reverse process of prestraining at a low temperature and testing at the high temperature. In addition to the work done on 2SO they also prestrained pure aluminum, copper, 65/35 brass, and 18/8 stainless steel at room temperature before testing at a low temperature. The flow stress of each of these materials also showed a great dependence on strain history.

PURPOSE OF PRESENT INVESTIGATION

This investigation was conducted in order to clarify some of the problems discussed above. A low carbon $2\frac{3}{4}$ pct silicon steel was selected for the investigation. Test series were conducted to determine the following:

1. Effect of testing temperature on the properties of the $2\frac{3}{4}$ pct silicon

FIG 2—Effect of prestraining in tension at room temperature on the retained ductility at a low temperature (-190°C) obtained on annealed steels.

FIG 3—Effect of prestraining in tension at room temperature on the transition temperature of an annealed (coarse grained) 0.20 to 0.25 pct carbon steel (Davidenkov and Sakharov).

steel, to determine the basic effects of testing temperature on the mechanical properties of this metal.

2. Effect of prestraining at room temperature on the properties at various low temperatures.

3. Effect of prestraining at various temperatures on the properties at a constant low temperature.

4. Effect of prestraining at various low temperatures on the properties at room temperature.

Material and Equipment

MATERIAL

The mechanical properties of ordinary low and medium carbon steels behave in general quite peculiarly with varying temperature. As discussed in a later section, most steels, when the temperature of testing is reduced, become considerably stronger while their ductility is only slightly affected over wide limits. However, at some low temperature the ductility drops to very small values over a narrow temperature range. In an investigation of the type proposed here, a steel whose fracturing characteristics behaved in this complex manner would impose a considerable limitation on the results that could be obtained. Consequently, a 2¾ pct silicon steel was selected for this work. The steel, which approached a solid solution type alloy, had the following analysis: C, 0.031; Mn, 0.12; P, 0.011; S, 0.015; Si, 2.73; Ni, 0.098; Al, 0.23; Cu, 0.116; Sn, 0.008. This steel also possessed the advantages that its ductility at room temperature was quite high, while it decreased to a very low value at the lowest temperature obtainable. A high silicon steel of this type also possesses very uniform flow and fracture characteristics.

form of ¾ in. rods had been annealed at 1450–1500°F for 8 hr, so that it possessed quite a large grain size. The steel was used in this “as-received” condition.

EQUIPMENT

The prestraining and testing was done on a 10,000 lb Riehle tensile test machine. All room temperature strains were accomplished with the use of a specially designed loading fixture that yielded an eccentricity of loading of less than 0.001 in. and a radial strain gauge reading in 0.0001 in.⁹ These same loading fixtures were adapted for the low temperature work under which

condition the eccentricity was slightly higher. A remote reading mechanical gauge reading in 0.0001 in. was also developed to be used with this apparatus. A detailed description of this equipment is given in another report.¹⁰

Procedure and Method of Evaluation

PRESTRAINING AND TESTING PROCEDURE

All specimens used in this investigation were initially machined to a 2-in. contour radius at the reduced section, to enforce fracturing at a predetermined location and to facilitate measuring the strains at the neck. The other specimen dimensions are shown in Fig 6.

Specimens that were tested at temperatures less than -78°C (that is, -80 , -100 , -120 , -150 , and -196°C) were finished by polishing in such a manner that the scratches on these specimens were in the direction of the axis of the specimen. Specimens that were prestrained and then tested at temperatures less than -78°C were polished after prestraining. In this series of tests, specimens that were prestrained to less than approximately 30 pct were polished to a 2-in. radius. If the specimens were prestrained to

FIG 4—Stress-strain curves for 1020 steel at a high and a low temperature and for prestraining at a high temperature and testing at a low temperature (Hollomon).

more than 30 pct, the contour radius of the strained specimen was determined, and the specimen was polished to this radius. This procedure removed approximately 0.005 in. from the diameter.

All tests were made with the speed of the movable head of the tensile machine approximately 0.04 ipm so that for each specimen strained, a large number of gauge readings could be taken at different loads in order to enable point by point recording of the stress-strain curves. (This, of course, was not possible at temperatures at which the coolant was frozen.) These readings yielded values of the average or "true" stress,* and of the average decrease in diameter of the minimum section. The diameter reduction was converted into the natural maximum strain, ϵ_1 , according to the equation:

$$\epsilon_1 = \frac{\text{Original area}}{\text{Instantaneous area}} - 1 = 2 \ln \frac{\text{Original diameter}}{\text{Instantaneous diameter}}$$

From these data a stress-strain curve was obtained for each specimen strained, showing the true stress as a function of the natural strain. In all instances these natural strains, therefore, relate to the dimensions of the specimen at the beginning of a particular straining operation. However, the use of natural strains made possible the addition of the prestrains and testing strains by the simple graphical operation of plotting the respective stress-strain curves side by side.

In the testing operation, particular care was exercised to observe the load at the moment of fracture so that the fracture stress† could be evaluated. The corresponding fracture strain or "retained ductility" was determined by diameter measurements made with a micro-comparator before and after straining.

METHOD OF EVALUATION

The evaluation of the test data was based primarily on the following two types of graphical representations:

1. A comparison of stress-strain curves obtained at a given temperature for various amounts of prestrains at several different temperatures, see Fig 16 to 21.

2. The dependence of the retained ductility at a given temperature upon the magnitude of prestrain, with the

* The true stress was defined as the ratio of the load to the minimum area of the specimen at the instant at which the load was obtained.

† True stress at fracture.

FIG 5—Effect of alternately straining at room temperature and at -196°C on the flow stress of a high conductivity copper (Orowan).

FIG 6—Tensile test specimen.

temperature of prestrain as parameter, see Fig 11 and 15.

These data were obtained, as mentioned before, on tensile test specimens having an initial longitudinal contour radius of two inches. This initial contour and the fact that the specimens developed necks on straining undoubtedly influenced the measured values of stress and ductility. However these effects of specimen shape are superimposed on the phenomena being discussed in this paper, and the measured average stresses and strains appear satisfactory. Furthermore, the principal conclusions derived relate to comparatively small strains and should, therefore, be only slightly influenced by the process of necking.

Discussion of Results

EFFECTS OF TESTING TEMPERATURE ON THE PROPERTIES OF THE UNSTRAINED MATERIAL

For the purpose of this investigation, it was first necessary to investigate the direct effect of testing temperature on the flow and fracture characteristics of the selected steel. Wherever possible, stress-strain curves were determined, which are plotted in Fig 7 and 8. The dependence of the yield strength (1 pct),* the tensile strength, and the

* The yield strength was defined as the stress at 1 pct permanent set instead of the conventional value of 0.2 pct, since the strain gauge used at low temperatures yielded more reliable values at this higher strain.

FIG 7—Effect of testing temperature on the stress-strain characteristics of a 2 $\frac{3}{4}$ pct Si steel.

FIG 8—Effect of testing temperature on the stress-strain characteristics of a 2 $\frac{3}{4}$ pct Si steel.

fracture stress upon temperature is shown in Fig 9 and that of the ductility in Fig 10. In both Fig 7 and 10 approximate values of the maximum load strains are also indicated. It can be seen from the stress-strain curves in Fig 7 and from Fig 9 that the value of yield strength changed with temperature at an approximately constant rate over the entire range investigated. The general shapes of the various stress-strain curves in Fig 7 are rather similar. With decreasing temperature, the stress-strain curve moved to higher stresses, increasing its slope, $ds/d\epsilon_1$,* only very slightly. The maximum load strain (which depends upon the relative slope, $ds/sd\epsilon_1$) consequently decreased slightly with decreasing temperature. (See Fig 10.)

The tensile strength, like the yield strength, also changed with temperature at an approximately constant rate down to a temperature of -130°C . The tensile strength values then went through a maximum at about -150°C .

At room temperature the silicon steel curves exhibited a slight but dis-

* Where s = average tensile stress, and ϵ_1 = maximum natural strain.

FIG 9—Effect of testing temperature on the strength properties of a 2 $\frac{3}{4}$ pct Si steel.

tinct yield point jog, or reversal in curvature at small strains, as apparent from the conventional stress-strain curves in Fig 8, which are plotted on an enlarged scale.* Fig 8 also includes several stress-strain curves taken at temperatures of -78 and -196°C . (These were the only low temperatures at which reliable small strain measurements were obtained.) The stress-strain curves for -196 and -78°C showed no indication of a yield point jog. It may be concluded, therefore, that the reversal in curvature of the stress-strain curves of the silicon steel decreases with decreasing temperature until it disappears somewhere before -80°C .

The ductility (contraction in area converted to natural strain) of the silicon steel decreased according to Fig 10 with decreasing temperature. At approximately -130°C the ductility became equal to the maximum load strain and at still lower temperatures it rather gradually approached very small values. At the lowest temperature used, -196°C , the steel was still distinctly ductile. (See Fig 8 and 10.)

*The pairs of stress-strain curves in Fig 8 represent tests obtained on pairs of randomly selected specimens at each temperature.

FIG 10—Effect of testing temperature on the ductility of a 2 $\frac{3}{4}$ pct Si steel.

The fracture stress changed with temperature in a manner which showed this property's dependence on both the flow stress (yield strength) and ductility. (See Fig 9 and 10.) This explains the rather slow decrease in fracture stress in the range below room temperature, where the relative change in ductility was also comparatively small. At lower temperatures the (average) fracture stress decreased at nearly a steady rate, to become slightly more than one half of the room temperature value at -196°C .

EFFECT OF PRETRAINING AT ROOM TEMPERATURE ON THE FRACTURING CHARACTERISTICS AT VARIOUS LOW TEMPERATURES

Fig 11 shows the ductility values retained after specimens were prestrained various amounts in tension at room temperature and then tested to failure at various low temperatures.

The retained ductility values went through a minimum, the magnitude of which was proportionally larger the lower the testing temperature. Thus, for example, at -196°C the ductility dropped from $2\frac{1}{2}$ pct with no prestrain to approximately 0.01 pct at

FIG 11—Effect of prestraining in tension at room temperature on the retained ductility at various low temperatures.

FIG 12—Effect of prestraining in tension at room temperature on the properties obtained at -196°C.

FIG 13—Effect of prestraining at various temperatures on the retained ductility at -196°C .

4 pct prestrain. At -100°C the ductility decreased from about 47 pct at zero prestrain to about 41 pct at a prestrain of 4 pct. At the highest temperature used in testing (-40°C), the minimum disappeared.

These curves also showed a maximum at the lower temperatures which gradually disappeared as the testing temperature was increased. At the lowest temperature used, -196°C , the maximum value of retained ductility (at 18 pct prestrain) was approximately 4 pct. This value was distinctly larger than the ductility of the unstrained metal which averaged only $2\frac{1}{2}$ pct. It also appears that the prestrain value at which this maximum occurred moved to lower prestrains as the testing temperature was increased.

The data presented here confirmed previous test results in that a considerable ductility was generally retained at low testing temperatures even though the magnitude of the prestrains at the high temperature exceeded the total ductility of the steel at the (low) temperature of testing. Only when the prestrain approached its limiting value, that is, the ductility at room temperature, did the ductility retained at the testing temperature also approach zero. Thus, in the range of large prestrains the retained ductility decreased gradually from its maximum value to the value of zero at a prestrain equal to the room temperature ductility.

Fig 12 represents stress-strain curves obtained after prestraining at room temperature and testing at -196°C . These curves are plotted so that their position on the strain axis indicates the magnitude of prestrain. From these curves it can be seen that the points of fracture defined a smooth continuous function of the total strain. The considerable variations in retained ductility, therefore, affected the fracture stress only slightly. The decrease in

fracture stress after small prestrains, frequently observed in previous investigations at -196°C , was therefore either absent or very small for the silicon steel. After prestrains larger than a few the percent, fracture stress increased rapidly with increasing prestrain up to a strain of $\epsilon_1 = 0.30$. After this value of prestrain, the increase in fracture stress became much slower. This can be explained by the increasing depth and sharpness of the neck beyond strains of $\epsilon_1 = 0.30$. Since the ductility retained at this temperature is quite small, the fracture stress should not only be a function of the strain, but also of contour (depth and sharpness) of the neck. Consequently, at high values of prestrain the specimen shape

may account for the low fracture stress values.

EFFECT OF PRESTRAINING AT VARIOUS TEMPERATURES ON THE FRACTURE CHARACTERISTICS AT A CONSTANT LOWER TEMPERATURE

In Fig 13 the ductility retained at -196°C after prestraining at $+20$, -100 , and -120°C , respectively, is plotted as a function of the prestrain. Small prestrains at any of these temperatures reduced the retained ductility to very small values which do not permit definite conclusions regarding any effect of the prestraining temperature. At larger prestrains, however, the ductility was found to be larger the

FIG 14—Effect of prestraining at various temperatures on the fracture stress at -196°C .

FIG 15—Effect of prestraining at various low temperatures on the retained ductility at room temperature.

FIG 17—Effect of prestraining at -60°C on the flow characteristics at room temperature.

higher the prestraining temperature, as was to be expected from the results of the first group of tests discussed above.

Fig 14 shows the fracture stress values obtained in these three test series, at the temperature of -196°C . According to this graph, the fracture stress appears to be independent of the prestraining temperature, and only a function of the magnitude of strain. This would be in agreement with some data by Hollomon¹¹ in which a pearlitic steel was prestrained at various temperatures between -110 and $+20^{\circ}\text{C}$ and then tested at -190°C . However, from the fact that the ductility values appeared definitely dependent upon the temperature of prestraining, the conclusion must be drawn that this also applies to the fracture stress. On the other hand, these resulting differences in fracture stress would be very small for the small ductility values observed, assuming that the stress-strain curve is determined only by the magnitude of prestrain. As shown later, this assumption probably does not apply, and this may also cause differences in the fracture stress. Apparently, both these effects are of sufficiently small magnitude to be hidden in the general

scattering of the test results.

EFFECT OF PRESTRAINING AT VARIOUS LOW TEMPERATURES ON THE FRACTURING CHARACTERISTICS AT A HIGH TEMPERATURE

The effects of prestraining at various low temperatures on the ductility retained at the high (room) temperature are shown in Fig 15. It appears that prestraining at any low temperature up to strains close to failure is no more damaging to the metal than if the same strain is accomplished at room temperature. The retained ductility values at room temperature decreased so that they were always equal to the total ductility in testing minus the prestrain. Only at high values of prestrain very close to the ductility of the steel at the temperature of prestraining did the straining appear slightly more harmful at the low temperature than the same strain would have been if the entire test had been conducted at room temperature. This applies to all three temperatures of prestraining.

Since the material used for the -60°C prestrains had slightly different properties than that used for the -78

and -120°C prestrains, two different 45° lines are given in Fig 15.

EFFECTS OF PRESTRAINING ON THE FLOW CHARACTERISTICS

The plastic flow characteristics of a metal are represented by the general shape of its stress-strain curve or, more specifically, by the initial value of the yield strength and the slope of the curve or strain-hardening rate. Consequently, an evaluation of the effect of prestraining on the flow characteristics was based on a determination of the effect of prestraining on these two characteristics. Furthermore, this analysis is based on the fact that straining at any single temperature simply uses up a portion of the initial stress-strain curve equivalent to the magnitude of the prestrain.

A number of stress-strain curves obtained on the silicon steel after prestraining at a temperature higher than the testing temperature are given in Fig 16, and curves after prestraining at different temperatures lower than the testing temperature are presented in Fig 17 to 19. For reasons of clarity the fundamental changes in the stress-

FIG 20—Schematic representation of the effect of prestraining at a high temperature on the flow characteristics at a lower temperature.

strain curves are also schematically shown in Fig 20 and 21. According to these graphs, prestraining at a temperature different from that of testing results in a stress-strain curve distinctly different from that obtained on straining at a constant temperature. These effects are in close qualitative agreement but possibly considerably smaller than those found in other metals.

It can be seen from Fig 16 and 20 that after prestraining at a relatively high temperature the yield strength at the low temperature is considerably reduced from the value that would have been obtained on straining at the low temperature. The subsequent rate of strain hardening, however, is larger after prestraining at the high temperature. Consequently, further straining in testing progressively reduces these deviations both in flow stress and in strain hardening. Both effects increase with increasing prestrain. Consequently, the deviations of the flow characteristics after high temperature prestraining from those after straining at the testing temperature disappear at comparatively small testing strains, if the prestrains are small.

According to Fig 17 to 19 and Fig 21, prestraining at a relatively low temperature causes effects diametrically opposite to those discussed above for

prestraining at a relatively high temperature. The yield strength is raised and the rate of strain hardening is reduced.* Generally, however, these deviations disappear rather rapidly on further straining. It should be expected, furthermore, that the discussed effects increase with increasing difference between prestraining and testing temperature. The test results are not quite conclusive but, in general, in agreement with this expectation.

Conclusions

Based on the test data obtained on this silicon steel, certain conclusions can be drawn on the effect of straining a ferritic material at one temperature on the fracture and flow characteristics at some other temperature.

As far as the *fracturing characteristics* after prestraining at a higher temperature than the testing temperature are concerned, the phenomena observed in these tests are similar to those previously reported for annealed steels. Prestraining small amounts at room temperature caused the retained ductility values at a low testing temperature to pass through a minimum when

*This particular effect may result in a yield point jog which is illustrated more clearly in the conventional stress-strain diagrams in Fig 22, for the same tests illustrated by Fig 18.

FIG 21—Schematic representation of the effect of prestraining at a low temperature on the flow characteristics at a high temperature.

FIG 22—Effect of prestraining at -78°C on the conventional stress-strain characteristics at room temperature.

determined as a function of prestrain. The test data presented here further indicated that the magnitude of this minimum decreased as the temperature difference between the prestraining temperature and the testing temperature was decreased. This behavior of cold worked annealed steels was tentatively correlated with the phenomenon of an uneven yielding illustrated by the yield jog in a tensile test. The correlation was based on the assumption that plastic flow apparently becomes increasingly uniform (at small strains) with decreasing testing temperature.

At sufficiently large prestrains the retained ductility went through a maximum, after which it again decreased at a rate such that the retained ductility did not become zero until the ductility was completely exhausted in prestraining.

A few additional test data indicated that if cold worked material was tested at a low temperature at which the material was still ductile, the retained ductility at this temperature was found to be greater the greater the ductility under the conditions of prestraining.

The fracturing characteristics after prestraining at a low temperature and testing at room temperature appeared to obey a simpler law than that discussed above. It appeared that prestraining at any low temperature was no more harmful than the same magnitude of strain conducted at room temperature until the prestrain values were very close to failure, (Fig 15).

The effects of prestraining at one temperature and testing at another temperature on the flow characteristics for this annealed steel appeared to conform to the behavior of various other metals and alloys, which behavior was discussed in the Introduction. However, the magnitude of the effects was distinctly smaller for this ferritic material (body-centered cubic) than for other metals which crystallize in the face-centered cubic lattice. This can be tentatively correlated with the stress-strain curves, the general appearance of which is less changed with temperature for ferritic materials than for face-centered cubic metals.

The above investigation only reveals a small portion of the laws which

govern the mechanical properties of a ferrous metal subjected to straining, under conditions where the temperature is not kept constant. So far, such practically important conditions have attracted little attention in the laboratory. The present investigation has shown clearly that no predictions can be made from any tests carried out at a constant temperature on the performance of the same metal when the strain-temperature history varies in a more general manner.

Relation between Chromium and Carbon in Chromium Steel Refining

D. C. HILTY,* Member AIME

Introduction

It has long been known that in melting high-chromium steels, some of the carbon might be oxidized out of the melt without excessive simultaneous oxidation of chromium, and that higher temperatures favor retention of chromium. The advent of oxygen injection as a tool for rapid decarburization of a steel bath permits significantly higher bath temperatures, and it was quickly recognized that the use of oxygen injection facilitated the oxidation of carbon to low levels in the presence of relatively high residual chromium contents.

Up to the present time, however, specific data pertaining to the chromium-carbon-temperature relations in chromium steel refining have not been available. Individual steelmakers have evolved practices more or less empirically, but there has been very little real basis for predicting how effective any given practice can be in permitting maximum oxidation of carbon with minimum loss of chromium.

The current investigation, therefore, was undertaken in an effort to establish the fundamental carbon-chromium relationship in molten iron under oxidizing conditions. As reported below, the equilibrium constant and the influence of temperature on that constant have been derived for the iron-chromium-carbon-oxygen reaction in the range of chromium steel compositions with what appears to be a fair degree of precision. The practical application of the result will be obvious.

Experimental Procedure

The laboratory investigation was carried out on chromium steel heats melted in a magnesia crucible in a 100-lb capacity induction furnace at the Union Carbide and Carbon Re-

search Laboratories. The charges for the heats consisted of Armco iron, low-carbon chromium metal, and high-carbon chromium metal, the relative proportions of which were calculated so that the various heats would contain from approximately 0.06 pct carbon and 8 pct chromium to 0.40 pct carbon and 30 pct chromium at melt-down. When the charges were melted, the bath temperatures were raised to the desired level, and the heats were then decarburized by successive injections of oxygen at the slag-metal interface through a 1/2-in. diam silica tube at a pressure of 30 psi. The duration of the oxygen injections was from 30 sec to 2 min. at intervals of approximately 5 to 30 min. It did not appear that length or frequency of the injection periods had any significant effect on the results; consequently, no effort was made to hold them constant and they were controlled only as was expedient to the general working of the heats. Between successive injections, the heats were sampled by means of a copper suction-tube sampler that yields a sound, rapidly-solidified sample representative of the composition of the molten metal at the temperature of sampling. This sampling device is a modification of the one described by Taylor and Chipman.¹

An attempt was made to vary bath temperatures between samples, but it quickly became evident that, unless the variations were small or unless the new temperature was maintained for a minimum of 15 min. during which an injection of oxygen was made in order to accelerate the reactions, a

very wide departure from equilibrium resulted. For most of the runs, therefore, temperature was maintained relatively constant at approximately 1750 or 1820°C. A few reliable observations at other temperatures, however, were obtained.

Temperature Measurement

The high temperatures involved in this investigation were measured by the radiation method, utilizing a Ray-O-Tube focused on the closed end of a refractory tube immersed in the metal bath. The immersion tubes employed were high-purity alumina tubes specially prepared by the Tonawanda Laboratory of The Linde Air Products Co. These tubes were quite sturdy under reasonable mechanical stress at high temperature. They were unusually resistant to thermal shock, and chemical attack on them by the melts was slow. With care, it was found possible to keep these tubes continuously immersed in a heat for as long as 5 hr at temperatures up to 1850°C, before failure by fluxing occurred.

The Ray-O-Tube—alumina tube assemblage was similar to those supplied commercially for lower temperature applications. In operation, the alumina tube was slowly immersed in the molten metal to a depth of approximately 5 in., and the device was then clamped solidly to a supporting jig where it remained for the duration of the run. A photograph of the equipment, in operation with Ray-O-Tube in place and oxygen injection in progress, is shown in Fig 1.

When in position in a heat, the instrument was calibrated by means of an immersion thermocouple and an optical pyrometer. For calibration through the range of temperatures from 1500 to 1650°C, a platinum—platinum + 10 pct rhodium thermocouple in a silica tube was immersed alongside the alumina tube. Output of the Ray-O-Tube in millivolts and the

FIG 1—Experimental setup employed.

temperature indicated by the thermocouple were plotted logarithmically. At the same time, the optical pyrometer was standardized against the thermocouple by removing the Ray-O-Tube from its holder and sighting the optical pyrometer on the end of the alumina tube. The calibration was then extended to temperatures above 1650°C with the optical pyrometer.

It was observed that the depth of immersion of the alumina tube had a definite effect on the calibration of the Ray-O-Tube. This was probably at least partially due to the fact that the Ray-O-Tube was equipped with a lens that covered too large a field for the diameter of the alumina tube; but since the Ray-O-Tube was calibrated for each individual run, and the calibration was checked during the course of the runs, possible error due to the depth of immersion effect is considered to have been minimized.

A typical calibration curve is illustrated in Fig 2. It is evident that a fairly accurate calibration was obtained. From this and the calibration curves for the other heats, it appeared that most of the temperature measurements were within $\pm 10^\circ\text{C}$ of the actual temperature.

FIG 2—Typical Ray-O-Tube calibration curve.

Observations and Determination of Equilibrium Constant

The carbon and chromium contents and the temperatures of the samples obtained are listed in Table 1 and were plotted to give the equilibrium curves shown in Fig 3.

The oxidation of carbon from a steel bath containing chromium is limited by the simultaneous oxidation of the chromium. Whether decarburization is carried out by ore additions or by injection of gaseous oxygen, the oxygen content of the bath is limited by the formation of an oxide of chromium. Up to the present time, it has been assumed that this oxide is either Cr_2O_3 or $\text{FeO} \cdot \text{Cr}_2\text{O}_3$, and that at one atmosphere pressure of carbon monoxide the limiting reaction is

so that the equilibrium constant would be approximately defined as

$$K_1 = \frac{\text{pct Cr}^2}{\text{pct C}^3} \quad [1a]$$

* Conventionally, underlining of the symbols in a steelmaking reaction indicates that those substances are dissolved in the iron.

or
$$K_2 = \frac{\text{pct Cr}^2}{\text{pct C}^4} \quad [2a]$$

These assumptions, however, are not supported by the present experimental evidence. The slope of the curves in Fig 3 is approximately unity, a fact

which strongly indicates that the actual constant is expressed by the equation,

$$K = \frac{\text{pct Cr}}{\text{pct C}} \quad [3a]$$

Equilibrium constants calculated according to Eq 3a are given in the last column of Table 1. It is evident that at constant temperature these K 's are truly constant well within the limits of experimental error.

Two explanations for this departure from the previously accepted hypothesis described by reactions 1 or 2 are suggested. The first is that reactions 1 or 2 do actually represent the equilibrium involved, but that the activity of carbon dissolved in the melt is greatly reduced by the presence of chromium so that it is not proportional to the concentration. This, of course, is possible and is in accordance with the principles of classical thermodynamics; but it seems somewhat improbable in a system that is in reality very far from being saturated with chromium carbides, in view of the magnitude of the effect at moderate chromium concentrations.

The second explanation presumes that the oxide of chromium directly involved is not Cr_2O_3 but CrO , so that

the reaction is

the nonmetallic phase being saturated with CrO and the CO pressure being approximately one atmosphere. At the temperatures of the experiments, the postulation of chromium monoxide does not appear to be unreasonable; it has previously been employed by Chen and Chipman² to account for some of the discrepancies observed in a study of the iron-chromium-oxygen system; CrO was suggested by Clark³ as the oxide of chromium formed during the decarburization of chromium steel heats by magnetite ore; and according to Körber and Oelsen,⁴ chromous oxide is the chief oxide of chromium occurring in acid slags in contact with molten iron-chromium alloys. Moreover, reaction 3 fits the observations without any complications regarding the activities of carbon or chromium. It is, therefore, considered that reaction 3 and Eq 3a are the most probable representations of the limiting equilibrium in the refining of chromium steels.

Effect of Temperature

The equilibrium constants calculated by Eq 3a were plotted logarith-

FIG 4—Effect of temperature on the equilibrium constant, $K = \frac{\text{Pct Cr}}{\text{Pct C}}$

mically against the reciprocal of the absolute temperature as illustrated in Fig 4.

The equation of the resulting curve is calculated to be

$$\text{Log } K = -\frac{15,200}{T} + 9.46, \quad [4]$$

in which T is the absolute temperature in degrees Kelvin.

If published⁵ thermal data for the carbon-oxygen reaction and the solution of chromium in molten iron be combined with the heat of reaction 3 calculated from Eq 4, a value of $-106,750$ cal per g mol is obtained for the heat of formation of CrO from the elements. This heat of formation, of course, is subject to considerable uncertainty, but it appears to be quite reasonable; it is of the same order of

magnitude as the heat of formation of manganous oxide, MnO , as, presumably, it should be. Therefore, it seems to be additional evidence in support of the hypothesis stated by reaction 3.

With Eq 4, the carbon-chromium relationship in liquid chromium steel under oxidizing conditions can be calculated for any temperature. This was done for what was believed to be the probable range of steelmaking temperatures as shown in Fig 5. For convenience, the temperatures appearing in Fig 5, and subsequently in this paper, have been converted to Fahrenheit scale in accordance with accepted commercial usage.

Several random observations of chromium and carbon contents at the end of the oxidizing period in commer-

cial arc-furnace heats were available and these were superimposed on the curves of Fig 5 in order to estimate the temperatures attained in commercial practice. Fig 6 illustrates the result.

From Fig 6, it is evident that the heats refined by conventional oreing methods attained temperatures averaging approximately 3025°F . As would be expected, heats made by oxygen practice were considerably hotter—large heats averaging 3275°F and small heats (less than 12 tons) about 3375°F . The maximum temperature appears to be on the order of 3400°F . In this connection, it is notable that in two of the heats, shown in Fig 6 as attaining temperatures close to 3400°F , serious damage to the furnace refractories occurred.

FIG 5—Chromium-carbon relation in chromium steel refining.

Conclusions

The conclusions drawn from this investigation are as follows:

1. It has been found that at constant temperature the relation between carbon and chromium in chromium steel refining can be expressed by the equilibrium constant,

$$K = \frac{\text{pct Cr}}{\text{pct C}}$$

2. The probable reaction is believed to be:

3. The effect of temperature on the relation has been derived and may be defined by the equation:

$$\log K = -\frac{15,200}{T} + 9.46$$

The Densification of Copper Powder Compacts in Hydrogen and in Vacuum

CHARLES B. JORDAN* and POL DUWEZ*

Introduction

THE phenomenon of the change of volume of pressed powder compacts upon sintering is well known in the field of powder metallurgy. Depending upon the metal or metals involved and the pressure used in forming, a compact may, in the course of time of sintering at a given temperature, expand monotonically, contract monotonically, or first show a volume change of one sign followed by a change of the opposite sign. It is clearly desirable to have accurate knowledge of the magnitude and sign of the change in dimensions to be expected in any given case, both from the point of view of direct usefulness in the fabrication of parts by powder metallurgy, and from the longer range viewpoint of elucidating the fundamental mechanism of metallic sintering.

The present study was therefore undertaken as a first step in acquiring systematic and reasonably quantitative knowledge of the change in density of metal powder compacts during sintering. For practical reasons, copper was selected as the material to be studied first, and its densification followed as a function of temperature and time of sintering in hydrogen and in vacuum.

Experimental Procedure

The copper powder used was that designated by the manufacturer (Metals Disintegrating Co., Elizabeth, N. J.) as MD-151. This powder was sifted through Tyler standard screens to separate the fraction having particle size range between 200 mesh and 325 mesh, and this fraction was used in all the subsequent work. Compacts weighing about 10 g were then pressed in a 1 in. diam round die, using a pressure of 20,000 psi throughout.

Sintering was carried out in commercially built electric furnaces in which the resistance windings are so disposed as to produce a nearly uniform temperature along the axis of the furnace for a length of about 18 in. centrally located. In order to be able to sinter in a controlled atmosphere, a 2 in. stainless steel tubing was inserted in the furnace. Each end of the tube was cooled by a water jacket about 7 in. long, and closed with a rubber stopper. The hydrogen used for one series of specimens was purified as described in Ref. 1. For the other set, a pressure of about 0.5 mm Hg was maintained during sintering by a Welch Duo-Seal pump.

The specimens were heated on square trays made of stainless steel. In placing specimens in the trays, a thin even layer of powdered aluminum oxide was first sprinkled on the bottom of the tray. A copper guard disk about half the thickness of the specimen was then placed in the tray and covered with a second layer of alumina. The actual specimen was then set on the guard disk, and a final coat of alumina sprinkled over the specimen.

This technique was evolved for sintering the specimens in such a way as to reduce the influence of unknown extraneous factors to a minimum. If the specimen is placed directly on the tray and sintered, it is found that the

resulting shape is that of a frustum of a cone, rather than a section of a right circular cylinder, since friction with the tray prevents the bottom of the specimen from contracting at the same rate as the top. In the arrangement used in these experiments, the guard disk provided a support which shrank at the same rate as the specimen, and the alumina powder reduced to a minimum friction between guard disk and tray, and between specimen and guard disk.

The procedure followed in sintering consisted of bringing the furnace to the required temperature, and then inserting the specimen into the central heated portion of the furnace tube in one of the two atmospheres used. At the end of the heating period, the specimen was cooled by bringing it into a portion of the furnace surrounded by a water jacket. These manipulations were carried out without opening the furnace, by means of rods which were attached to the trays and operated through a sliding seal in the rubber stopper.

The progress of densification of the copper compacts was studied at 1300, 1400, 1500, 1600, 1700, and 1800°F. At each of these temperatures, a specimen was allowed to sinter for each of the following time intervals: ½, 1, 2, 4, 8, 16, 32, and 64 hr. The thickness and diameter of each specimen were measured with micrometers before and after sintering, and each was weighed on an analytical balance after sintering.

Results

The techniques described in the preceding section were found to give satisfactory results. The specimens were not detectibly warped after sintering, and were usually of uniform diameter (that is, truly round) to within ± 0.001 in., a very few showing a variation in diameter of ± 0.002 in. All specimens were found to have the same diameter

FIG 1—Densification parameter vs. sintering time in hydrogen.

before sintering (namely, 1.039 in.) as was to be expected, since all were pressed in the same die. It was not possible to maintain the same uniformity in thickness, because of slight variations in the amount of powder weighed out, and because of friction in the die during pressing. However, the variation in thickness at various points on a given specimen did not exceed ± 0.004 in., and variations from one specimen to another were of no importance, since the change in dimensions of each was followed separately.

From the measured values of mass, thickness, and diameter of each specimen before and after sintering, the value of the "densification parameter" (defined and explained in the next section of this paper) was calculated. The values of this parameter are plotted as a function of time for the various temperatures used in Fig 1 and 2.

Discussion of Technique

The method of cooling used may appear inadequate in view of the precautions commonly taken in metallurgical work to obtain a very rapid quench. It must be remembered, however, that there is no question of retaining a high temperature structure in the experiments described in this report, and that the only reason for quenching is to define the time of sintering. The water-jacket cooling used certainly accomplishes this end with no greater error than that necessarily introduced at the start of sintering by the time required for the specimen to heat to the required temperature, and possesses the great advantage of keeping the specimen flat and round.

The error introduced by filing the edges of the specimen also requires some consideration. In computing the density, the volume of each specimen was calculated from the measured thickness and diameter, assuming the specimen to be a right circular cylinder. Because of the chamfered edges, the calculated volume will obviously be larger than the true volume, and when used in conjunction with the true mass will give too low a value for the density. In order to estimate this error, several specimens were weighed before and after chamfering. It was found that the specimens which were filed lightly (duplicating conditions of the actual test specimens on which densification measurements were made) lost about 0.5 pct of their mass, while a specimen which was deliberately filed much more heavily than any of those used in the actual tests lost about 1 pct of its mass. This error was therefore considered negligible.

Interpretation of Results

Although the work described in this report was primarily undertaken as an investigation of the sintering of metals, it is important to note that the process actually observed is not one of pure sintering. When a powdered metal compact is heated, not only do the particles gradually bond together, but also the overall volume changes. In the case of the present work on copper, a monotonic shrinkage is observed, the porosity progressively decreasing and the voids becoming smaller and fewer. Evidently this process involves mechanisms other than those of sintering; for example, the overcoming of pressure in the voids due either to gas trapped during pressing, or to volatile impurities present. For this reason, it is more accurate to refer to the progressive shrinkage of copper compacts studied in this work as "densification" rather than as "sintering," since sintering is not the only process taking place. Nevertheless, it is possible to obtain information about sintering by this type of experiment, and it is moreover of practical importance to study sintering under the conditions which exist in the case of powdered metals.

The maximum density which a powder compact can attain is obviously that of the solid metal. This circumstance provides a natural scale on which the progress of densification can be measured. By comparing the observed change in density with the maximum possible change, a convenient dimensionless parameter is obtained, the value of which is initially zero and which becomes unity if the compact attains its maximum possible density.

FIG 2—Densification parameter vs. sintering time in vacuum.

FIG 3—Relation between time and reciprocal of temperature for various values of densification parameter; hydrogen sintering.

Specifically, the “densification parameter” σ is defined as follows:

$$\sigma = \frac{\rho - \rho_0}{\rho_\infty - \rho_0} \quad [1]$$

where ρ = density after partial sintering

ρ_0 = initial density (before sintering)

ρ_∞ = maximum possible density, that is, density of the solid metal.

It is in terms of this parameter that the experimental results are plotted in Fig 3 and 4.

The ultimate goal of the investigation, of which the experiments described in this paper are the first step, is to elucidate the mechanism by which metals bond or sinter together as a result of the application of pressure and heat at temperatures below the melting point. Several hypotheses as to the nature of this mechanism have been advanced (see, for example, Ref. 2, 3, and 4). While no such fundamental theory is developed in this paper, it will be shown that the results of the experiments described may be given a simple interpretation which may serve as a useful guide to future theoretical and experimental investigations.

Briefly stated, it appears possible that densification can be interpreted as a rate process such as that involved, for example, in chemical reactions. Such processes are characterized (see, for example, Ref. 5) by the fact that if a given state is attained in a time t_1 at absolute temperature T_1 , and in time t_2 at some different absolute temperature T_2 , then these four quantities are connected by the relation

$$\log_e \left(\frac{t_1}{t_2} \right) = \frac{Q}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \quad [2]$$

where R is the gas constant (1.99 cal per mol-°C), and the constant Q is the molal “heat of activation” or “activation energy.” As applied to chemical reactions, for example, Q is proportional to the minimum energy which a molecule must have in order to take part in the reaction (see Ref. 5 for details). In the present case, the progress of the densification “reaction” is measured by the value of the parameter σ . Consequently, to see whether densification may be regarded as a rate process, it is necessary to plot curves of constant σ on a graph of $\log t$ vs. $1/T$, when, if the above relation is to be satisfied, straight lines must

result. Fig 3 and 4 show curves of constant σ plotted in this fashion with the best-fitting straight line drawn through each set of points for comparison. These lines form an approximately parallel set for each of the two sintering atmospheres used, the set representing sintering in vacuum having a larger slope than the set for sintering in hydrogen. The two slopes correspond to values of Q of about 128,000 cal per mol for vacuum sintering, and 80,000 cal per mol for hydrogen sintering, corresponding to the fact (see Fig 1 and 2) that a given time and temperature produce a lower value of σ in vacuum than in hydrogen. A possible explanation of this result is that the hydrogen atmosphere cleans the oxide film from the surface of the particles by reduction, thus making it easier for the clean surfaces to bond together.

It should be noted that there appears to be a systematic deviation of the points from the straight lines drawn in Fig 3 and 4, and that therefore the present results are certainly not conclusive proof that densification is a rate process. It seems plausible, in fact, that densification is the result of superposition of several more fundamental proc-

FIG 4—Relation between time and reciprocal of temperature for various values of densification parameter, vacuum sintering.

esses, each of which may be a rate process governed by a different energy of activation. The fact that the overall result may be approximately described as a single rate process would then seem to indicate that one of the fundamental processes predominates over the others.

Summary and Conclusions

From the results of the experimental work described in this paper, it appears that the densification of copper powder compacts in hydrogen and in vacuum may be approximately described as a rate process governed by a heat of activation. The agreement of such a description with the data, however, is not sufficiently good to permit a definite assertion of its validity, and it is suggested only as an hypothesis which may be a useful guide to further work.

The fact that copper powder compacts densify more slowly in vacuum than in hydrogen indicates that the oxide film on the surface of the particles influences the rate of densification. Accordingly, the next step in the experimental investigation will be to study the densification of compacts pressed from powder which has been cleaned of oxide by reduction in hydrogen. It would also be very desirable to investigate the densification of compacts made from powder of more closely controlled particle size, and it is hoped that the practical difficulties involved in obtaining such powder may be overcome sufficiently to permit some work along this line.

Influence of Composition on the Stress-corrosion Cracking of Some Copper-base Alloys

D. H. THOMPSON* and A. W. TRACY,* Members AIME

SEASON-CRACKING is a type of failure of brass that results from the simultaneous effect of stress and certain corrodants. The object of this paper is to present data that will aid in a more complete understanding of the mechanism of season-cracking and related phenomena. Results presented show that certain high copper alloys are susceptible to season-cracking or stress-corrosion cracking, and possible explanations are discussed. Starting at least as far back as 1906, many papers have been devoted to this subject but the symposium¹ held in Philadelphia in 1944 is the richest source of information.

In order to study season-cracking, several of the many variables were held constant so as to learn the effects of others. Season-cracking is generally understood to refer to the corrosion cracking of brass having internal stresses;^{2,3} it is a special case of the general stress-corrosion cracking. Inasmuch as applied stresses are more readily produced and controlled, they were used exclusively in this research and the resulting phenomenon must be called stress-corrosion cracking.^{2,3} Only constant tensile stresses were used. The agents believed to be most frequently responsible for season-cracking are ammonia, amines and compounds containing them. Both moisture and oxygen also appear to be necessary. Therefore, an atmosphere containing ammonia, water-vapor and air was selected for these tests.

Briefly, the work consisted of exposing sheet metal specimens, having a reduced section $\frac{1}{4}$ by 0.050 in., of copper-base alloys to the effect of static tensile stresses between 5,000 and 20,000 psi and simultaneous contact with a continuously renewed atmosphere containing 80 pct air, 16 pct ammonia and 4 pct water vapor at 35°C. The gas mixture and the speci-

mens were maintained above the dew-point. The time-to-failure in minutes was the primary measure of results. In order to limit the experiment to finite time, it was considered that a specimen which had neither failed nor undergone microscopically detectable cracking in 40,000 min. (4 weeks) while under a stress of 10,000 psi or more could be considered immune to cracking. This is merely a convenient limit and is not to be considered proof of immunity. Supplementary tests in the absence of stress using weight loss or microscopical appearance as measures of attack were made.

Apparatus

The apparatus used in this research is shown in Fig 1. To facilitate the description it may conveniently be divided into six parts: stress-producing units, test chamber, gas train, electrical controls, timers and gas analysis device.

A stress-producing unit is shown in an exploded view at the left in Fig 2. At the right is an assembled unit with a specimen in place in the lower portion; it is this part that remains in the ammonia atmosphere during a test. The upper part contains a spring, a central threaded rod, a large nut and necessary washers, pins, and so forth. Stress is produced in the specimen by

screwing down the top nut against the spring, thus putting a tensile load on the central rod and so on the specimen. The wrench that turns the nut by extending through the upper cap, is seen at the upper right of the figure. The magnitude of the load is gauged by measuring from the pin that extends through the side of the tube, to a fixed point on the large flange. Measurement is made with a vernier beam caliper, shown at the right of the figure. The necessary spring compression to give a desired stress is calculated from the calibration curve of the spring and the dimensions of the specimen.

The test chamber, center Fig 1, consists of a thermally insulated steel box 32 in. long by 10 in. high by 7 in. wide. A horizontal baffle reaching nearly to each end divides the chamber equally. Below this baffle are inlets for air and ammonia, a heating coil and a fan. Thus the gases are warmed and mixed in the lower level and flow past the specimens in the upper level. A thermostat and thermometer project into the upper space. The top is pierced by 12 ports flanked by $\frac{3}{8}$ in. threaded studs. A test starts when a port is opened and a unit containing a stressed specimen is thrust through it and bolted down against a neoprene gasket. The test chamber is held at 35°C.

The gas train, right rear Fig 1, carries ammonia and air continuously to the test chamber. Tank ammonia passes through two reducing valves, a needle valve, a flow meter and into the test chamber. The air from either the plant compressor or a small laboratory compressor passes through wool towers and flow controls to the flow-meter. It then bubbles through water at 34°C and through a heated line to the test chamber.

Electrical controls, left rear, Fig 1, provide rectifiers and mercury relays for the test-chamber and humidifier-heating-control circuits and outlets for

FIG 1—Apparatus for stress-corrosion cracking in moist ammoniacal atmosphere.

gas-line heaters, cover heater, fan and timers.

Timers occupy the space in front of the test chamber. They comprise 12 Veeder-Root counters operated by cams on a shaft driven by a 1 rpm Telechron motor. When a specimen breaks it releases a string which drops a weight stopping a counter. The life of that specimen in minutes is then directly available.

Analysis of the gases contained in the test chamber is performed at the outlet at the right-hand end. The mixed gases are drawn through an absorption train. In the first absorber a known amount of sulphuric acid neutralizes and removes ammonia from the mixture. The moisture is then absorbed in the second tube, which contains silica gel. The volume of air remaining is measured with an aspirator. The gain in weight of both absorption tubes less the known weight of ammonia gives the weight of water. Both ammonia and water are recorded as ml per 500 ml of air, which is the volume per minute delivered to the chamber.

Preparation of Specimens

The following metals and alloys were tested:

- Oxygen-free high-conductivity copper
- Tough-pitch copper
- Copper-zinc alloys containing 0–40 pct zinc
- Copper-phosphorus alloys containing 0–0.9 pct phosphorus
- Copper-arsenic alloys containing 0–1.2 pct arsenic

- Copper-antimony alloys containing 0–1.0 pct antimony
- Copper-silicon alloys containing 0–4 pct silicon
- Copper-nickel alloys containing 0–30 pct nickel
- Copper-aluminum alloys containing 0–8 pct aluminum

Analyses of these alloys are given in Table 1.

The alloys were cast and rolled in the laboratory or obtained from mill production. When possible they were finished with a 50 pct reduction by cold rolling to 0.050 in. gauge. They were sheared to $\frac{3}{8}$ in. by 5 in. and the reduced section filed by the use of a hardened-steel jig to $\frac{1}{4}$ in. by 0.050 in. Holes were drilled near the ends. The specimens were then annealed, usually at 500°C for one hour. Annealing scale was removed by suitable pickles, usually dilute nitric acid, but in every case

FIG 2—Stress-producing unit.

the final dip was cold 20 pct sulphuric acid. After a thorough water rinse the specimens were dipped in alcohol and dried in a blast of hot air. After being measured, they were inserted in units and loaded to the desired stresses. The upper end of each specimen passed out of the test chamber and the opening around it was sealed with wax; the

lower end was held with a pin, which was also imbedded in wax to prevent attack of the specimen at this highly stressed point. Before exposure the whole unit, including the specimen, was warmed to prevent thermal condensation. As each unit was lowered into the test chamber, the appropriate counter was started.

Results

COPPER

Three types of substantially pure copper were subjected to stress-corrosion in the moist ammoniacal atmosphere without the occurrence of cracks. These were tough pitch, OFHC and copper prepared in the laboratory by melting Chile cathode copper under charcoal and pouring through city gas. The magnitude of applied stresses and the length of the exposures are given in Table 2. The column headed "Penetration" describes the result of microscopical examination of a longitudinal section up to an exposed surface. In only one case had any localized corrosion taken place, and in no case was there any evidence of cracking or intergranular penetration.

Table 2 . . . Copper in Moist Ammoniacal Atmosphere Did Not Break Under Stress Within Time Indicated

| | Alloy No. | Stress PSI | Time Min. | Penetration |
|--------------------------------|-----------|------------|-----------|-------------|
| Tough Pitch Copper | 1 | 5,000 | 50,000 | None |
| Touch Pitch Copper | 1 | 10,000 | 50,000 | One Pit |
| Tough Pitch Copper | 2 | 10,000 | 40,000 | None |
| OFHC Copper | 3 | 10,000 | 40,000 | None |
| Copper | 4 | 10,000 | 40,000 | None |
| Copper (4 specimens) | 5 | 15,000 | 50,000 | None |

COPPER-ZINC ALLOYS

Results obtained from copper-zinc alloys are presented graphically in Fig 3. The breaking times of specimens stressed at 5,000, 10,000 and 15,000 psi are plotted against the zinc content in per cent. The corrosion rate in inch per year (ipy) is also plotted against zinc content. Corrosion rate figures were computed from weight loss data on specimens exposed without stress to the same moist ammoniacal atmosphere. It is obvious that the resistance to cracking decreases rapidly as the zinc content increases. The corrosion rate, while relatively stable, does drop slightly with the cracking time, suggesting that the alloys which crack more rapidly are those that corrode less rapidly. Table 3 includes these data and also gives the microscopically observed intergranular penetration that occurred in the unstressed specimens.

Two things should be noted especially: the lack of correlation between cracking rate and corrosion rate, with the suggestion of negative correlation,

and the occurrence of intergranula penetration in the absence of stress.

COPPER-PHOSPHORUS ALLOYS

Similar results are shown in Fig 4 for copper-phosphorus alloys, although at only one applied stress, 10,000 psi. Comparison of Fig 4 with Fig 3 shows that the curves are similar in shape; the breaking time decreases sharply when either phosphorus or zinc is added to copper. An impressive difference is the extreme rapidity with which the breaking time drops as phosphorus is added. For instance, Table 4 gives 274 min. as the breaking time for the 0.1 pct phosphorus alloy (Alloy No. 22) under 10,000 psi stress in the moist ammoniacal atmosphere, while copper with no phosphorus does not break in 50,000 min. even at higher stresses. Comparison with Table 3 shows that this 0.1 pct phosphorus alloy breaks nearly as rapidly as 80-20 brass under the same conditions.

Table 4 also reveals the rapid attack of the moist ammoniacal atmosphere on annealed copper-phosphorus alloys without stress. A sample containing 0.24 pct phosphorus (Alloy No. 23) was annealed at 800°C for one hour and exposed to the moist ammoniacal atmosphere without stress. After 40,000 min. (1 month) it was found that the intergranular penetration had completely penetrated the 0.050 in. gauge sheet. The specimen could be broken apart into individual grains with the fingers. Some of the grains are shown in Fig 5, a micrograph taken at 30X. Fig 6 is a micrograph taken at 75X of a piece of 0.1 pct phosphorus alloy (Alloy No. 22) that was annealed at 800°C and exposed without stress to the

moist ammoniacal atmosphere for one week. The depth of penetration is obvious.

The results on the phosphorus alloys are extremely interesting. The addition of phosphorus to copper has a profound effect on the rapidity of stress-corrosion cracking and also on the rate of intergranular penetration in moist ammoniacal atmosphere in the absence of stress. The effect cannot be explained by the removal of oxygen from the copper since OFHC and copper deoxidized with some other elements do not crack. The changes in mechanical and physical properties are negligible except in the case of conductivity and the overall corrosion rate is but slightly affected.

Alloy No. 25 (0.92 pct phosphorus) broke less rapidly than alloys with intermediate phosphorus contents; it is beyond the solid solubility limit of phosphorus in copper. This upswing will be observed in other alloy systems, to be described.

In Fig 3 and 4, points are very close to the axes, but Tables 3 and 4 give the actual values that the points represent. No change in scale was adopted because of the advantage of having all the graphs use the same vertical scale.

COPPER-ARSENIC ALLOYS

Stress-corrosion cracking and corrosion rate curves from data on copper-arsenic alloys in moist ammoniacal atmosphere are shown in Fig 7. These curves are quite different from those presented for copper-phosphorus and copper-zinc in that there is a pronounced minimum in the cracking

curves at 0.2 pct arsenic and a maximum in the corrosion-rate curve at 0.05 pct arsenic. The 1.2 pct arsenic alloy is immune to cracking within the prescribed limits. Table 5 shows that intergranular penetration is appreciable after four weeks in the lower arsenic alloys. The effect of arsenic content on

cracking time is not nearly as pronounced as in the case of phosphorus and zinc and it extends over only a very narrow range.

COPPER-ANTIMONY ALLOYS

Fig 8 gives the results for copper-antimony alloys. The minimum cracking time is greater than with the alloy systems previously considered. There is some evidence of a minimum in the antimony per cent versus cracking-time curve. There is a maximum in the corrosion-rate curve. Intergranular penetration is shown by Table 6 to be appreciable in one week.

COPPER-SILICON ALLOYS

Results are given in Fig 9. There is a distinct minimum cracking time at 1 pct silicon, which is a higher percentage than in the case of arsenic. Immunity appears at 4 pct silicon. The corrosion rate is fairly constant. Intergranular penetration given in Table 7 is definite but only after four weeks.

COPPER-NICKEL ALLOYS

Fig 10 gives test results. The minimum in the cracking time is pronounced but the required exposure is long. With this system, as with others, a maximum appears in the corrosion rate curve at a more dilute composition than the minimum in the breaking curve. At 30 pct nickel, the corrosion rate is very small; the samples were hardly tarnished at the end of a week. Table 8 shows that intergranular penetration is almost absent, but it does occur.

COPPER-ALUMINUM ALLOYS

Fig 11 shows a minimum breaking time at 1 pct aluminum. The corrosion-rate curve is relatively constant with only a slight maximum. Intergranular penetration is small in one week as given in Table 9.

OTHER TESTS

In line with Dix's⁴ theories on the role of grain-boundary precipitates in rendering an alloy subject to stress-corrosion cracking, some tests were made to try to show whether the effect is important in copper-phosphorus alloys. About 0.5 pct phosphorus is soluble in copper, but iron phosphide is believed to be only slightly soluble in copper. Therefore, the attempt was made to precipitate iron phosphide and study its effect on cracking. Two alloys were cast; each contained 0.024 pct phosphorus. One contained 0.002 pct iron and the

other contained 0.006 pct iron (alloy Nos. 57 and 58). Thermal treatments were designed to produce precipitation in the grain bodies, in the grain boundaries and to maintain solution. Microscopical examination of these specimens at 1000 diam revealed scattered spheres of some precipitate in all of them in about equal amount. The results of stress-corrosion cracking tests in moist ammonia vapor are given in Table 10. While there is apparently a trend indicating that metal treated to produce precipitation in the grain bodies is most resistant to cracking, followed by material with maximum solution and then that treated to produce grain-boundary pre-

cipitation, there is no difference between the alloy having 0.002 pct iron and the one containing 0.006 pct iron. The statistical procedure, analysis of variance, has been applied to these data and the conclusion is reached that no significant difference exists among them. Either the thermal treatment produced no precipitation, or the sub-microscopic precipitate had no large effect on the breaking time.

Another experiment was performed to show the effect of long-time anneals on the stress-corrosion cracking rate. The results are given in Table 11. The alloy contained 0.1 pct phosphorus, balance copper (alloy No. 22). Four samples were annealed at 500°C for one hour and in addition two of them were held for 64 hr at 350°C. While the long anneal produced a somewhat shorter cracking time, the difference is not significant in the face of the variation among supposedly identical specimens. At 1000 diam these samples also showed tiny, randomly distributed spheres of precipitate, the number of which was not greatly affected by the low temperature anneal. It is believed that such material has not been absorbed from segregation occurring in the casting, because of the relatively small amount of working and annealing of small laboratory castings. More work should be done in connection with the effect of heat treatment on the stress-corrosion cracking of this type of alloy.

PATH OF CRACKS

Although ammonia cracking in brass is usually largely intergranular, there are exceptions in alpha brass as well as in other alloys. Fig 12 at 500 diam

shows typical intergranular cracking in ½ in. diam 70-30 brass rod (alloy No. 60) that failed under 5,000 psi in moist ammoniacal atmosphere. Radically different is Fig 13 at 500 diam, which shows cracking in arsenical admiralty (alloy No. 59) after the same preparation and exposure as the brass. It is difficult to find cracks that are intergranular in this micrograph. The 70-30 brass was annealed at 500°C and the admiralty brass at 550°C for one hour. Similar transcrystalline cracking has been observed in arsenical and non-arsenical admiralty and aluminum brass. Fig 14 is a micrograph at 250 diam of a 65-35 brass gear (alloy No. 62) that was sheared from ¼ in. wrought stock and then exposed to moist ammoniacal atmosphere for 48 hr. The cracks have a strong tendency to pass through the grains.

Fig 15 taken at 500 diam shows cracks in an alloy containing 1.5 pct silicon, 1 pct manganese (alloy No. 61) which failed under 20,000 psi stress in moist ammoniacal atmosphere. Cracks, besides being intergranular, have a tendency to follow twin boundaries, or slip planes.

Discussion of Results

In 1930, Bassett⁵ stated that he had seen copper season-crack, while in 1944 Edmunds⁶ reported that copper is immune to mercury and ammonia stress-cracking. These statements are not necessarily contradictory. Bassett referred to service failures of copper tubes, which are usually deoxidized with phosphorus. Such failures are not frequent but the authors have observed a number of them. One such tube is

Table 11 . . . Effect of Heat-treatment on the Season-cracking of Copper Containing 0.1 Pct Phosphorus in Moist Ammoniacal Atmosphere

shown in Fig 16. It is a 1½ in. od by 0.082 in. ga wall, hard copper tube containing 0.019 pct phosphorus. In service, presumably a refrigeration plant, it was wrapped in tar paper, twine and two layers of hair felt. The line of the edge of the tar paper is shown as a helical row of pits, and the cracks are obvious. The present paper indicates that phosphorus-deoxidized copper cracks readily under the test conditions. Presumably the paucity of service failures of phosphorus-deoxidized copper is due to the low yield point of copper, which makes the occurrence of high internal stresses impossible. The authors have found no evidence that tough pitch or OFHC copper is subject to season-cracking or to stress-corrosion cracking in moist ammoniacal atmosphere and they therefore agree with Edmunds's statement.

As mentioned above, Dix⁴ suggested that season-cracking is due to corrosion that is accelerated by the potential between grain boundaries and grain bodies and that this difference is caused by the precipitation of an insoluble phase at the grain boundaries and the depletion of the solute atoms surrounding the grain boundary. There seems to be no evidence to support the existence of a precipitated phase in brass. Nor is there evidence of a change in the breaking time curve when the solid solubility of zinc in copper is exceeded. Read, Reed and Rosenthal⁷ attribute this potential difference rather to the high free energy of regions of lattice imperfection such as grain boundaries.

The behavior of phosphorus-deoxidized copper described in the present paper suggested that these theories be reconsidered. It will be recalled that 0.1 pct phosphorus is sufficient to allow rapid cracking of copper with which it is alloyed. Further, this alloy is subject to quite rapid intergranular corrosion in moist ammonia vapor in the ab-

sence of stress either internal or external. Thus grain boundaries are open avenues for corrosion by moist ammonia vapor when a little phosphorus is present, but they are closed to traffic when only copper is present. This behavior suggests to the authors that phosphorus is concentrated at the grain boundaries and whether within or beyond the solid solubility limit, the alloy in this region is anodic to the higher-copper grain-bodies. This potential may be the result of lattice dislocation; not that caused by the abutting of adjacent differently-oriented grains at the boundaries but

rather distortion around solute atoms of phosphorus. Such distortion is one of the causes for the large effect phosphorus has on the conductivity of copper.

The behavior of this alloy, if it be typical of season-cracking in general, allows some other conclusions to be drawn. Since intergranular penetration occurs in the absence of stress, it appears that stress merely accelerates the corrosive action of the ammonia, keeping the crack open and a fresh notch available for its action. Another possibility is the formation of protective films. It is conceivable that such

films would form first on the exposed surfaces of the grain bodies, leaving the boundaries highly anodic. In more concentrated alloys the film might cover the *whole* surface and stifle boundary attack. In all the systems studied, except copper-zinc, up to 40 pct zinc, there is at least an indication that the cracking rate decreases as the per cent of alloying element is increased.

The presence of 0.1 pct phosphorus in copper changes the mechanical properties only negligibly and it is impossible to correlate the cracking tendency with yield strength, propor-

FIG 16—1½ in. od by 0.082 in. gauge hard copper tube containing 0.019 pct phosphorus.
Cracked in service.

tional limit or the like.

It should be emphasized that these tests cannot be used as a basis for predicting service failures by season-cracking. The failures were produced under artificial laboratory conditions and should not arouse fears that phosphorized or arsenical copper tubes will crack in service except in rare instances.

Summary

These tests show that the addition of zinc, phosphorus, arsenic, antimony, silicon, nickel or aluminum to copper forms alloys that are subject to stress-corrosion cracking in moist ammoniacal atmosphere in some composition ranges.

The product of the cracking time and the per cent of the added element is an inverse measure of the cracking tendency per one per cent. From these figures the alloying elements may be formed into a rank of decreasing unit cracking tendency. This order follows: phosphorus, arsenic, antimony, silicon, zinc, aluminum, nickel. Brass cracks more rapidly than any of the other systems mentioned; but zinc is low on the list because so much of it must be added to give a rapid cracking rate.

Another observation is the appearance of a minimum in the per cent of alloying element versus breaking-time curve. This minimum breaking time is distinct in copper-nickel, copper-silicon, copper-arsenic, and cop-

per-aluminum systems; is indicated in copper-antimony and copper-phosphorus and is absent in copper-zinc.

The curves relating per cent of added element to corrosion rate in the absence of stress have a maximum in all systems for one of the more dilute alloys. This maximum is distinct in the copper-arsenic and copper-antimony systems and fairly distinct in copper-nickel, but only slight in the others. The same three, copper-arsenic, copper-antimony and copper-nickel, may be said to exhibit positive correlation between cracking tendency and corrosion rate.

Intergranular penetration in the absence of stress in moist ammoniacal atmosphere places the elements in the following rank in order of decreasing penetration: phosphorus, antimony, zinc, arsenic, silicon, aluminum, nickel. The extent of this phenomenon is very greatly dependent on grain size and the rank is subject to so many variables, that it may be assumed to be nearly enough like the breaking-time rank to support the belief of a common cause.

Conclusion

The data presented are insufficient for a concrete conclusion, but the following are offered for consideration:

The addition of a soluble element to copper produces a concentration of the solute at grain boundaries. This concen-

tration either forms a submicroscopic precipitate, a richer solid solution, or lattice disturbances. Any of these conditions makes the grain boundary region anodic to the grain bodies. Localized corrosion is accelerated and grain boundary penetration ensues. The presence of a tensile stress still further accelerates penetration by opening cracks and forming highly stressed notches.

Work is being continued on this research.

Acknowledgments

The authors are grateful to Mr. John R. Freeman, Jr., Technical Manager of The American Brass Co. for his encouragement during the experimental work and for permission to publish the results. They also wish to acknowledge the advice of Mr. E. W. Palmer and the assistance of many members of the technical staff of The American Brass Co.

Cadmium Recovery Practice in Lead Smelting

P. C. FEDDERSEN,* Member AIME, and HAROLD E. LEE*

Introductory Review

GREENOCKITE is the only known cadmium mineral of importance. It occurs rather universally, in minor concentrations, as a secondary mineral in sphalerite deposits. The world's cadmium output is obtained through the processing of metallurgical by-products, largely from the treatment of residues from electrolytic zinc, retort zinc and lithopone plants. These sources are supplemented by the processing of fumes from lead and copper smelting operations. The development of modern selective flotation practice in the decade 1920-1930, which permitted the economical mining of complex lead-zinc ores, resulted in significant increases in the quantities of cadmium entering lead smelting systems.

Being closely related to zinc as to occurrence, properties and production, most detailed description of cadmium recovery methods are to be found recorded in connection with zinc metallurgy. Other than occasional articles pertaining to particular operational procedures, literature offers but little in the nature of a balanced survey of lead smelter cadmium recovery practices. While many of the basic operations described for the recovery of cadmium from zinc by-products are applicable to the treatment of lead plant products, the inherent problems involved differ widely. In general the cadmium content of related by-products from routine lead smelting operations is present in lower concentrations, exists in a less soluble state and is associated with both a greater quantity and a greater variety of detrimental impurities. To cope with these problems, lead smelter practices are found

to follow the general outline:

Preparatory Processing

1. Concentration operations
2. Sulphation operations

Cadmium Plant Processing

1. Leaching operations
2. Purification operations
3. Sponge precipitation operations
4. Metal recovery operations
5. Refining and casting operations

As in the case of related zinc plant operations, cadmium recovery practices at lead smelters are not standardized. They not only vary as to type, but also extent. Depending upon prevailing conditions, lead smelter cadmium operations range from simple concentration campaigns, for the purpose of sufficiently "up-grading" products for shipment elsewhere, to complete processing steps for the production of refined metal.

Preparatory Processing

The cadmium content of lead smelter receipts is low and, as a rule, proportionate to the zinc content; the usual range of cadmium contained being of the order of 0.01-0.05 pct. Were it not for the low boiling point of cadmium, such small concentrations would, no doubt, be lost in the large tonnages of

slag, metal and other smelter end products. However, the ready volatility of cadmium and its compounds at prevailing lead smelting temperatures results in its concentration in fractional portions of fume collected. This collected fume comprises a circulating load within the smelter system.

Thus, the cadmium content of blast furnace fume* increases with each successive circulation until an equilibrium value is reached when the sum of the cadmium losses, due to handling and in slag, waste gases and other end products, becomes equal to the intake as ore. With ore receipts averaging, say 0.03 pct cadmium, the concentration value obtainable, through fume circulation in a routine manner, approaches 10-12 pct. In such operations, cadmium concentrations in blast furnace fume of from 3-5 pct are readily attainable. However, the concentration gain beyond this range, with each additional circulation, is progressively decreased as a result of mounting losses occurring through handling and in end products. Therefore, to avoid excessive cadmium loss and to enhance the ultimate concentration attainable, it is customary practice to isolate blast furnace fume at some intermediate cadmium content for special concentration procedure.

The most common type cadmium concentration "campaign" involves special smelting operations wherein a relatively high portion of blast furnace fume at 3-6 pct cadmium is incorporated into the sinter charge. This type practice is roughly illustrated by the diagram on p. 111.

Cadmium fume collected from lead blast furnace operations is not amen-

* The relatively low temperature and contact time which prevails during sintering operations is not conducive to cadmium volatilization. Practically all cadmium elimination occurs during blast furnace smelting operations.

able to direct acid leaching. The cadmium contained is only partially soluble and the fume possesses a sort of "buffer" action which often limits the concentration of dissolved cadmium attainable. It is general practice in the processing of blast furnace fume to "precondition" by pugging with large portions of concentrated sulphuric acid, followed by heat treatment for elongated periods. While this sulphation step effects a high degree of solubility and greatly aids in impurity control, the attendant acid requirement is high and the physical aspects of the operation are not too desirable. At Kellogg, where acid is expensive, the Bunker Hill Smelter developed an alternative concentration procedure whereby a product of high cadmium concentration, amenable to direct acid leaching, is obtained by the fusion of blast furnace fume with silica.

In the fusion process, as in the more common method described above, blast furnace fume is circulated in the regular lead smelting system until a cadmium concentration of 4-6 pct is reached. It is then removed, mixed

with a siliceous flux and fused in a special reverberatory operation. During the fusion, the bulk of the cadmium is distilled and the bulk of the lead retained as a silicate slag. Lead silicate slag is tapped and returned to the blast furnace; the cadmium fume is bag filtered, then sacked for delivery to a cadmium leach plant. In reverberatory melting, the grade of cadmium fume produced is limited by the necessity of excessive temperature in the upper bath layer. However, by limiting the proportion of silica used, and with reasonable care to avoid over-firing, blast furnace fume of 4-6 pct cadmium content may be raised to a product of 30 pct grade.*

At this point in our presentation of cadmium recovery procedures, it should be stated that descriptive terms such as "common," "customary," and so forth, are only used in their most limited sense; departures from the

* In experimental tests under closely controlled temperature conditions such as are readily attainable in an electric furnace, cadmium fume of 60 pct grade has been produced from blast furnace fume containing 6-8 pct cadmium.

practices featured are many. Some of these diversions are itemized below:

TRAIL SMELTER—CONSOLIDATED MINING AND SMELTING CO. OF CANADA, LTD., TRAIL, B. C.

Cadmium-bearing fume from routine lead smelting operations, of 3-5 pct Cd. grade, is periodically forwarded to the zinc oxide leach plant and processed in conjunction with zinc fume from slag treatment operations. The insoluble lead-rich residue is subsequently returned to the lead smelting circuit.

FEDERAL PLANT—AMERICAN SMELTING AND REFINING CO. ALTON, ILL.

Up until 1941, at least, no special concentration campaigns were utilized. Blast furnace fume at about 5 pct cadmium was sulphated directly with concentrated sulphuric acid in preparation for subsequent leaching.

Some of the American Smelting and Refining Co. plants no doubt, practice cadmium concentration in accordance with an assigned patent² granted to R. Teats in 1930. This patent specifies the treating of a finely divided mixture of lead fluedust, carbonaceous material and limestone at 825-850°C to boil off cadmium which is oxidized and collected. The limestone, it is claimed, hinders the volatilization of lead and zinc.

PORT PIRIE WORKS—BROKEN HILL ASSOCIATED PTY., LTD., PORT PIRIE, AUSTRALIA¹

Blast furnace fume from routine lead smelting operations is continuously advanced to a central sump and agitated with water for the solution of fractional portions of the cadmium present. The pulp is then subjected to vacuum filtration, giving two products: (1) Residue, which is returned to the blast furnace and (2) Filtrate, which is treated with sodium carbonate for the precipitation of dissolved cadmium. The cadmium carbonate precipitate is filtered, dried and shipped to the Electrolytic Zinc Co. of Australasia, Ltd., at Risdon.

Survey of Cadmium Production Methods at Lead Smelters

As already indicated, lead smelter METALS TRANSACTIONS . . . 111

Table 1 . . . Outline of Representative Processes for the Production of Cadmium from Lead Smelter Fume

| Plant and Location | U. S. Smelting, Refining and Mining Co. Midvale, Utah | St. Joseph Lead Co. Herculaneum, Mo. | Bunker Hill and Sullivan Mining and Conct. Co., Kellogg, Idaho |
|---|---|---|---|
| Preparatory processing Concentration | Blast furnace fume is circulated in routine manner until reaching cadmium content of 3-6 pct. It is then removed and incorporated in relatively high proportions in sinter charge. Blast furnace smelting of resultant sinter gives a fume product containing 15-25 pct cadmium | Similar to Midvale practice | Blast furnace fume is removed from regular circuit at 4-6 pct Cd., then mixed with siliceous flux and fused in a reverberatory furnace. Furnace products consist of lead silicate slag (returned to blast furnace) and cadmium fume at 25-30 pct Cd. |
| Sulphation | Above fume is pugged with 60° Be H ₂ SO ₄ in batches (400 lb acid per 800 lb fume). After digestion period mixture is charged to furnace and baked 24 hr at low red heat, discharged, cooled and dry ground to 20-mesh in a 3 ft ball mill. | Fume at about 20 pct Cd. Pugged in batches with about 210 lb. 60° Be H ₂ SO ₄ per 500 lb fume. Mixture is charged in 2,000 lb batches to a pan mounted on wheels. Charged pan is rolled on tracks into furnace and baked (no rabbling) for 8 hr at 850°F, then discharged, cooled and broken, and pulverized to -100 mesh. | None |
| Cadmium plant processing Leach Purification | Joint leach and purification practiced. Minus 20-mesh sulphated product is leached with spent electrolyte for 2 hr in a 4 × 8 ft Pachuca tank. Na ₂ S is added to ppt. Cu and final slurry is neutralized with hydrated lime, then filtered and washed in a 2-ft sq. Shriver press. Washed cake is returned to lead smelting circuit. | Pulverized sulphated product is leached in a mechanical agitated, 2,000 gal capacity steel tank with wash water from previous filter operations, then filtered and washed in 3-ft sq. Shriver press. Washed cake returned to lead circuit. Filtrate is treated with a limited quantity of zinc dust for ppt. of Cu and then passed through a clarifier. | Joint leach and purification practiced. Concentrated fume is subjected to a direct dilute H ₂ SO ₄ leach, 800 lb H ₂ SO ₄ being consumed per 6,000 lb of 27 pct cadmium fume. Fe, Sb, As, etc., purification effected by the addition of copperas and oxidizer in conjunction with pH control. Slurry is filtered and washed in a 65 cf capacity Shriver press. Washed cake is returned to lead smelting circuit. |
| Sponge precipitation | None | Pregnant Cd filtrate is drawn from storage tanks through two 4 ft × 2½ ft × 30 ft deposition tanks—each tank containing 96 - 21 × 12 × 2 in. plates. Cadmium ppt. as metallic sponge on zinc plate surfaces. Sponge is removed from tank, dewatered by a rough initial press, then briquetted at high pressure into 8 in. diam × 1 in. thick cakes which are stored under kerosene. | Pregnant solution is drawn from storage tanks in 800 gal batches to a conical-bottomed, high-speed agitation tank. The solution is acidified and treated with zinc dust for Cd sponge precipitation. Initial sponge washing is carried out by decantation and the final dewatering and wash in a Shriver press. Cd sponge is briquetted directly with a Stokes machine. |
| Metal recovery | Pregnant cadmium solution at 120 gpl electrolyzed down to 35 gpl in a cascade, side circulation, cell circuit. Five aluminum cathodes and six durion anodes used in each of 10-30 in. sq. × 40 in. deep California redwood cells. Cathode trees removed each shift, cathodes stripped each 24 hr 78-80 pct Cd at 12 amp per sq ft. Plant capacity = 450 lb cathode cadmium per day. | Cadmium briquettes retorted. Graphite bottles and cast iron condensers used. 3 retorts utilized per 2,000 lb Cd per day. 12 hr retorting time consumed per 500 lb charge. | Cadmium briquettes are retorted, using similar bottles and condensers as employed at Herculaneum plant. Four retorts are used per 1,500 lb of cadmium per day. Retorting time per 600 lb charge variable, depending upon life of bottle and grade of briquettes. Retort residue returned to leach. |
| Refining and casting | No additional refining practiced. Cathodes are rolled and rough melted under cylinder oil and cast into bars. These bars are then melted under a light caustic cover for casting into shapes for market. | Crude retort metal is subjected to two treatments; the first with ZNCl ₂ for the removal of thallium. The TI-bearing ZnCl ₂ is marketed and the metal then treated with NaOH prior to casting into shapes for market. | Crude retort metal is melted under a caustic cover residual from a previous melt. This cover is then drossed and the bath agitated with NH ₄ Cl for thallium removal. The chloride dross is skimmed and stored. New caustic is then added and melted, followed by a brief period of agitation prior to casting into shapes for market. |

cadmium operations vary, both as to type and extent. The tonnage intake is low and few smelters pursue operations beyond the concentration stage. Markets for resultant cadmium products of reasonable grade may be found in zinc and chemical industries, and the American Smelting and Refining Co. operate a custom cadmium plant at Denver, Colo. Cadmium bearing products from the various A. S. and R. smelting operations are shipped for treatment at the Globe Plant. Prominent among other lead smelters equipped for cadmium production are the U. S. Smelting, Refining and Mining Co. at Midvale, Utah,* the St.

Joseph Lead Co. at Herculaneum, Mo., and the Bunker Hill and Sullivan Mining and Concentrating Co. at Kellogg, Idaho. To a limited extent, in the past few years, the Bunker Hill plant has been operated on a custom basis.

Table 1 presents an outline of the essential processing steps employed in the three latter plants recorded above. This summary depicts a more or less representative composite of lead smelter practices. Among the component operations outlined may be found most processing steps employed for the recovery of cadmium from lead smelter fume. Though little information regarding recent practices at the Globe plant are available, earlier descriptions of H. R. Hanley³ and T. P. Campbell⁴ indicate no marked departures from the

practices summarized in Table 1. Since an intelligent discussion of a process requires intimate plant knowledge and an appreciation of prevailing plant conditions, any detailed considerations of the practices outlined must be limited to Bunker Hill operations. It is interesting to note, however, that the Midvale process, developed by R. H. Stevens,⁵ was placed in operation in 1915. This plant can probably be credited with the first production of electrolytic cadmium on a commercial scale.

Flow-sheet, Fig 1, was drawn from information supplied by the Bunker Hill Smelter and appeared in an article by John B. Huttie, "Bunker Hill Plant Recovers Metallic Cadmium from Fume," *Eng. and Min. Jnl.*, Apr. 1946, 174 No. 4, 82-85. It is reproduced by permission of *Eng. and Min. Jnl.*

* The Midvale Plant has not been operated since 1944.

Bunker Hill Cadmium Recovery Operations

GENERAL DISCUSSION

As already described under "Preparatory Processing" Bunker Hill Cadmium Plant feed consists of fume concentrated by a special reverberatory fusion of a mixture of blast furnace fume and siliceous flux. This product, produced under more favorable oxidiz-

ing conditions than practically attainable in a blast furnace, contains very little sulphide and is amenable to direct leaching in dilute sulphuric acid. As is illustrated by the accompanying flow-sheet, Fig 1, the process employed utilizes a combined leaching and purification operation, followed by sponge precipitation with zinc dust and final metal recovery by retorting. The particular type and sequence of methods depicted were selected after a long

experimental period during which many alternative practices were investigated.

Cadmium recovery obviously involves low tonnage operations wherein efficient processing is most essential to economic production. Processing efficiency is particularly important in the treatment of lead smelter fumes which generally contain high and variable percentages of troublesome impurities. In certain instances primary extraction becomes secondary to flow simplicity

FIG 2—Cadmium leach and precipitation tanks—showing hodding and ventilation system.

and flexibility. In the development of Bunker Hill practice for example, experimental experience indicated that the increased primary extraction attainable by means of separate leaching and purification steps, would not justify the attendant complications of plant flow and the associated increased treatment and capital costs. Similar evaluations resulted in the choice of distillation procedure over electrolysis and sponge precipitation with zinc dust rather than on slab zinc as practiced at Herculanum. For the processing of Bunker Hill fume, the degree of impurity control necessary for successful electrolytic operations would require re-solution of a thoroughly washed sponge in a separate electrolyte circuit. Retorting procedure not only avoided this extra treatment, but also provided operations more readily adjustable to variable capacity conditions. Although the Herculanum type precipitation practice produces sponge of superior retorting grade, such a system would be very cumbersome in the processing of arsenic-bearing products where venting is necessary and every precaution to avoid arsine poisoning must be taken.

GENERAL PLANT DESIGN

The Bunker Hill Cadmium Plant represents a modern installation for the

processing of lead fume, having been placed in operation in June, 1945. It is a compact steel and concrete structure, constructed for the production of 1000 lb of cadmium per day when treating fume of 25 pct grade. Into its design were incorporated all practical facilities to provide both operational ease and favorable working conditions. Equipment units are conveniently located and served by an excellent ventilation system. Solution levels in tanks are observable from strategic points by means of electronic level indicators. Retort temperatures are automatically indicated and recorded, and semiautomatic temperature control with a fuel-air ratio controller, is provided. Both the upper floor, utilized for the receipt and storage of fume and reagents, and the lower floor from which end products emerge, are readily served by truck. Material passes by gravity flow through the leaching, precipitation and metal recovery operations conducted on intermediate levels.

LEACHING AND PURIFICATION PRACTICE

Referring to the accompanying flow-sheet (Fig 1), sacked cadmium fume is weighed and dumped into a steel bin which is screw-discharged into a 3 × 3 ft pulping ball mill located on the leach floor. Circulating wash solution meets

and carries the screw-discharged fume into the scoop box of the pulping mill from which it flows by gravity into a vented, lead-lined, 8 × 8 ft agitator tank. (Fig 2.)

Prior to the flow of ball mill slurry, a predetermined weight of concentrated H_2SO_4 is drawn into the leach-tank along with a small volume of wash water and the agitator started. To this strong acid mixture is then added copperas and sufficient sodium chlorate to oxidize the iron to the ferric state. About mid-run, to offset the reducing effects of fume ingredients, additional chlorate is added at the ball mill and at the close of the run, some potassium permanganate.

While reagent consumption varies widely with changes in fume character, the consumption when treating 6000 lb of 26 pct cadmium grade fume* may be roughly recorded in the range of:

| REAGENT | POUNDS |
|------------------------|--------|
| 60° Be H_2SO_4 | 800 |
| Copperas..... | 200 |
| Sodium Chlorate..... | 30 |
| $KMnO_4$ | 10 |

About two hours is required to pulp 6000 lb of fume. Then, after a short period of additional agitation, the slurry is sampled for acidity. If its pH value runs much lower than 5.3, as shown by a Coleman pH tester, addi-

* Reagent proportions shown on the flow-sheet are for the treatment of high-grade cadmium fume (approx. 45 pct Cd).

FIG 3—Sixty-five cubic foot capacity Shriver press—utilized for both cadmium leaching and precipitation operations.

tional fume is added. Upon reaching the required acidity range, a filtrate sample is assayed for arsenic. When the arsenic assay shows the presence of less than 10 mg per liter, the slurry is diluted to about 1700 gal and pumped through a 65 cf capacity, closed delivery Shriver press, (forty-two 2 in. \times 3 ft square frames used), to one of two 5000 gal lead-lined, pregnant solution storage tanks. Seventeen hundred gallons of slurry results in about 1500 gal of pregnant solution. One leach cycle is completed per 2-man shift and about 10,000 gal of pregnant solution is obtained in six shifts' operation.

Purification is accomplished through the use of oxidizers and by pH control. Though copperas aids in arsenic removal; considerable arsenic precipitates as a cadmium compound, and the primary extraction attainable varies as the cadmium arsenic ratio; this ranges from a low of about 75 pct for products containing about 6-7 pct As to around 90 pct for products down to 3 pct As. Neutralization to a pH of 5.3 permits practically complete arsenic precipitation. While operations in a higher acidity range allow higher primary extraction, the arsenic purification problem is greatly complicated.

The leach residue is washed in the filter press with about 1500 gal of water which is pumped to an 8 \times 8 ft lead-

lined storage tank for use as make-up solution in a succeeding leach. Upon breaking the filter-press, the washed and blown residue is dropped through a chute to a concrete storage bin on the lowest plant level. From this bin it is conveyed back to the lead smelting circuit, wherein lead is recovered and the cadmium returned to the circulating fume load. (Fig 3.)

SPONGE PRECIPITATION PRACTICE

After two leach days, during which the solution of 8000 to 10,000 lb of cadmium is effected, the crew turns to precipitation operations. Stored pregnant solution, now of known cadmium content, is drawn in 600-800 gal batches into a lead-lined, conical-bottomed precipitation tank served by a high-speed agitator. As in the leach system, this tank is hooded and positively vented by means of a 6400 cfm fan. The vented tank atmosphere is conveyed and discharged into the blast furnace flue system. In this manner, possible hazardous concentrations of arsine are speedily removed and diluted to harmless proportions with 150,000 cfm of blast furnace gas.

Each batch of solution for precipitation is acidified by the addition of H_2SO_4 , to about 4.5 grams acid per

liter. Then, zinc dust is charged in the proportion of about 0.62 lb zinc per lb of cadmium contained. Electro-positive zinc displaces cadmium from solution with the production of cadmium sponge. The action, induced by high-speed agitation, breaks and rolls the sponge masses into dense pellets favorable to washing by decantation. To prevent the precipitation of basic sulphate salts, the solution acidity is not allowed to fall below 2.0 grams per liter and zinc additions are terminated when the solution assay shows a cadmium content below 0.5 grams per liter. At this point, the agitator is shut off, the pellets allowed to settle, and the clarified $ZnSO_4$ solution decanted and pumped to a strong zinc solution storage tank for marketing to the flotation mills of the district. The settled cadmium is then washed by dilution with water and agitation before being pumped to the Shriver press; the filtrate going to a weak $ZnSO_4$ storage tank for delivery to D and L sintering operations.

About 9 similarly treated precipitation batches are accumulated in the filter press prior to a final wash with water. The press is then blown with air until warm, broken, and the contents discharged to a steel storage bin on the retort floor below. To avoid excessive cadmium oxidation, briquetting op-

FIG 4—Stokes briquetting machine showing cadmium briquette storage pans.

erations are started soon after a press discharge.

METAL RECOVERY OPERATIONS

Sponge briquetting, with no additive agents and no prior treatment other than granulation through an 8-mesh screen, is practiced. The screened sponge is charged to the hopper of a Model R Stokes machine. The sponge is dewatered and its density increased about three times, by compression under 17 tons pressure, into 2 in. diam by $\frac{1}{2}$ in. thick briquettes. The compressed discs discharge into steel storage pans at the rate of about 1000 lb per hr. Each storage pan has a capacity equivalent to that of a retort bottle. They stand off the floor on legs to permit ready transfer to the retorts by lift truck. (Fig 4.)

Two oil fired retort units are employed for cadmium distillation from briquetted sponge. Each retort unit is of firebrick construction and contains two No. 11 American Crucible Co. graphite bottles set on piers above a brick checker-work arch, which distributes the heat from the firebox below. The retort bottles are manually charged, 600 lb per bottle, 1200 lb per retort unit.

After being charged, portable, partially insulated, cast iron condensers, which fit about the extended neck of the retort bottles, are rolled into place and the bottle-condenser junction sealed with fireclay. The closed, outer

ends of the cylindrical condensers have two $\frac{1}{2}$ -in. holes. The bottom hole is immediately sealed with clay and only opened when tapping metal. The upper hole is kept open for an hour or so after the start of a run to permit the escape of moisture and other gases noncondensable at elevated temperatures. When cadmium vapor is evidenced, the upper hole is sealed.

While the retorting cycle is a variable depending upon the bottle life and briquette character, the average time consumed approaches 20 hr. A description of Bunker Hill retorting practice is as follows:

With the condensers pulled aside, the briquette storage pans are moved to the retorts and the contents shovelled into the bottles. The condensers are then rolled into place and the junctions sealed with clay. Next, the firing is stepped up and the firebox temperature brought to, and maintained at, 2100°F. After about $1\frac{1}{2}$ hr heating, cadmium starts to distill and the upper vent holes are sealed. From then on, at three-hour intervals, the condensers are tapped and the condensed, molten cadmium drawn into steel pans. When the charge is "cooked" as evidenced from the quantity of metal drawn, the condensers are pulled away and the bottles raked clean for the receipt of the succeeding charge.

Retort residue is returned to the leach circuit and the crude metal is charged to one of two pots utilized for refining and casting. Depending upon

bottle life and the grade of briquettes, the operation of two retort units (four bottles) allows a crude metal production of from 1400 to 2000 lb of cadmium per day. (Fig 5.)

REFINING AND CASTING PRACTICE

Two 3000-lb capacity, electrically heated kettles are used for both refining and casting. One pot is being either held or used for casting while the other is being charged for refining. Refining operations are chiefly concerned with thallium removal. The crude retort metal produced meets all impurity specifications except for lead and thallium. All metal is treated for thallium removal; occasional lots destined for sale to bearing manufacturers must be redistilled to meet lead specifications.

Crude retort metal is charged to one of the two kettles and melted under a thin caustic cover. When the kettle is full, the caustic cover is skimmed and 30 lb of ammonium chloride is agitated into the bath over a $\frac{3}{4}$ -hr period. The chloride dross is then removed and 20 lb of new caustic added. About 15 min. additional agitation is given as a precaution against zinc contamination. At this point the agitator is removed and the metal ready for casting.

Refined metal is drawn, by means of a screw-operated valve, through an outlet in the kettle bottom into a casting ladle that is heated by means of a kerosene torch. It is cast into shapes

FIG 5—Bunker Hill cadmium retort installation—showing condenser in place and tapping operations.

for marketing in vertical, air-operated molds. The solidified shapes (slabs, balls, sticks) are given a dilute hydrochloric acid dip and wiped dry before weighing and boxing for shipment.

Cadmium Metal Marketing

There are no A. S. T. M. Cadmium specifications. Although attempts have been made in recent years to establish market requirements of more restricted and uniform nature, standardization has not yet been realized. In general, platers are rather lenient with regard to lead (0.05 pct max.) but are insistent on limiting the thallium content to 0.005 pct. The bearing manufacturers, on the other hand, are willing to accept up to 0.05 pct thallium but limit the lead content to 0.02 pct. Some of the diversified marketing specifications are illustrated in Table 2.

As pointed out by John L. Bray,⁶ cadmium is technically one of the younger metals. Although known since 1818, until comparatively recent times there have been but few uses for cadmium. Prior to 1925, the bulk of the world's cadmium was produced in Germany. Production in the United States, at that time, ranged between 25 and 100 tons per year. Concurrent with the use of cadmium as a plating medium, principally in the automotive industry, a marked growth occurred in U. S. production. By 1939, the United States became the world's largest producer.

While up-to-date statistics are unavailable at this writing, evidence points to a 1948 U. S. production approaching the 1947 total of 4,000 tons metallic cadmium. This production is somewhat under the war-time high of 4,300 tons, a decline that parallels a 10 pct decrease in zinc production from its war-time peak. At 4,000 tons per year, metallic cadmium production appears to be somewhat in excess of current domestic requirements. The pattern of current domestic consumption is of the following order:

| | Pct |
|----------------------|-----|
| Electro-plating..... | 75 |
| Bearing alloys..... | 15 |
| Solder alloys..... | 5 |
| Pigments..... | 2 |
| Chemical..... | 2 |
| Miscellaneous..... | 1 |

It is interesting to note that the foregoing pattern is not typical of

Table 2 . . . Marketing Specifications

foreign consumption. Abroad there is a more extensive use of cadmium in alloys and less in plating. About 10 pct of foreign consumption is also utilized in the manufacture of cadmium-nickel batteries for industrial and railroad units. This type battery has not been extensively used in this country, although within the past few years a small company in New England is reported to have started production.

Development of Muffle Furnaces for the Production of Zinc Oxide and Zinc at East Chicago, Indiana

GUNNARD E. JOHNSON*

Introduction

THE problem of efficient reclamation of zinc base die cast scrap became interesting early in 1930. Die Cast Metal, as referred to in this paper, is a zinc base alloy with various proportions of aluminum, copper, magnesium, antimony and tin.

Many attempts were made to work out some means of reclaiming the discarded die cast metal for re-use as new die cast metal. Difficulties in such reclamation were attributable to contamination by lead and tin from solder, chromium and nickel from electroplated coatings, and iron from iron inserts.

This paper relates the experiments that led to the development of a specialized muffle furnace for the treatment of zinc base die cast scrap for the production of zinc oxide and zinc, and describes the development of the muffle furnace and the equipment now used commercially for these purposes. The Eagle-Picher Co. acquired all patent rights¹ for these developments from the International Smelting and Refining Co. in connection with their purchase of the East Chicago Plant.

Zinc Base Scrap Situation

About 1935, the die cast scrap situation became increasingly acute for scrap dealers. This scrap was accumulating from dismantling automobiles and household appliances which contained die cast parts. Efforts to find an outlet for this type of scrap were intensified.

The International Smelting and Refining Co. began to study the possibilities of a commercial process for the recovery of values from die cast scrap. At that time most of the die cast metal

Table 1 . . . Distribution of Products Produced by Melting Die Cast Scrap

| | Weight in Lb | Per Cent of Weight Charged | Per Cent Zinc | Lb Zinc | Per Cent of Zinc Charged |

reclaimed was melted down in small kettles of from one to five tons capacity, the iron inserts being removed by skimming. The dross was skimmed off and disposed of as a zinc dross. The drossed metal was cast into slabs and was given the trade name "die cast slabs." Distribution of the products produced by melting die cast scrap in kettles is shown in Table 1.

American Process Experiments

A method considered for the production of zinc oxide from die cast scrap was an adaption of the standard American Process of zinc oxide manufacture. Thus some die cast scrap was mixed with oxidized zinc materials and charged to Wetherill grates. The zinc oxidized to zinc oxide but, while the aluminum and copper largely remained in the residue, the color of the zinc oxide produced was impaired by copper contamination. As the proportion of

die cast scrap was increased, liquation took place; that is, the metal trickled through the charge then solidified in the openings of the grates.

French Process Experiments

Several hundred tons of die cast scrap were purchased for test purposes and converted into die cast slabs. These slabs were charged into a French Process (horizontal retort) zinc oxide furnace with some electrolytic zinc. A satisfactory grade of zinc oxide was not produced.

Distillation in Belgian Retorts

It was then decided that, rather than attempt to use scrap die cast metal or scrap zinc for the production of zinc oxide, it would be advisable to redistill the die cast slab metal in a Belgian retort furnace.

The opportunity to do so was provided by the closing of the zinc smelter of the Illinois Zinc Co. at Peru, Ill. Arrangements were made for the operation of a Belgian retort furnace for such redistillation purposes. The results of this experiment are summarized in Table 2.

San Francisco Meeting, February 1949.

All of the zinc produced contained varying amounts of copper, tin and aluminum in sufficient quantities to make it unmarketable. The metals produced, however, were found satisfactory for use in making zinc oxide provided the quantities used were limited to a small fraction of the total metal charged.

Distillation in Graphite Retort Bottles

Some attempts were made to treat die cast scrap in graphite bottles to produce zinc. Very little success resulted from these attempts because graphite bottles had a short life. Also the relative position of the condenser with reference to the retort permitted the condensing metal to contact, and become contaminated with, aluminum and copper.

The next experiment was to produce zinc oxide from the die cast scrap charged to graphite retorts. The zinc oxide produced was conveyed directly to a baghouse by means of a fan and duct system. This zinc oxide was unsatisfactory because of the high copper content and very poor color. Further, contamination with lead and aluminum took place; these elements being mechanically carried into the baghouse when the mouth of the retort bottle was cleaned or when the charge of residue left in the bottle was poured into molds.

It was finally concluded that recognized processes for production of zinc or zinc oxide were not satisfactory for the treatment of die cast metal. Some new approach to the problem was needed.

Experimental Muffle Furnaces

Initial investigation began with the use of a laboratory muffle furnace. This was a rectangular muffle constructed of carborundum tile cemented at the joints. Attempts were made to hold the

level of liquid metal at not over 2 in. in depth. Even with this small depth of metal, serious leakage occurred.

At about the same time, a pilot unit was constructed which provided means for heating the metal bath from above and below. Heat was introduced below the bath by means of a gas flame within a refractory tunnel. This furnace leaked badly after every effort had been made to make it tight enough to contain molten die cast metal.

Shortly afterward a larger experimental unit 5 ft long with a carborundum arch 3 ft wide was built and tested. This unit is illustrated in Fig 1 which shows cross-sectional and longitudinal-sectional views of the furnace.

This pilot unit established the fact that zinc could be vaporized, practically, by means of a large shallow bath and that such vaporizing is less violent and more easily controlled than in the more restricted areas of small retorts.

This furnace provided a monolithic hearth construction arranged within a steel shell to confine the molten metal against escape and loss. Also, operation of the furnace confirmed calculations that it was practical to apply heat to the bath, from above, through a carborundum arch. The zinc vapor did not seep through the carborundum arch.

The metal was charged into the furnace through two small openings in the vaporizing chamber just below the arch. Zinc vapors were conveyed by a short horizontal brick flue to a chamber. Oxidation of the metal vapor to zinc oxide took place at the brick chamber from which the zinc oxide was conducted to a baghouse through a steel flue. This furnace established operating characteristics of the larger furnaces later constructed and pointed out the need for a substantial arch anchorage and related construction problems.

Our experience with these furnaces indicated that satisfactory commercial operations would not be achieved until an integrated unit was produced, having a tight hearth, a tight arch, and

adequate provisions for keeping the zinc or scrap metal heated to the desired temperature, in conjunction with a vaporizing unit from which zinc vapors would be discharged rapidly and at uniform rate. Analysis of experimental operations also led us to believe that commercial operations could proceed upon development of effective means for excluding air from the vaporizing chamber within which the molten bath was being heated. Any air entering this area would react with the vapors to form an oxide film or layer, which inhibits heat transfer to the bath of molten zinc, thus gradually impeding the liberation of zinc vapors from it. This factor was a principal cause of the decline in rate of oxide production soon after the start of operations in the experimental muffle units. It was recognized at the time that the results obtained in small scale equipment would not necessarily be predictive of those obtainable with a larger furnace. However, contemplation of a large scale unit introduced additional questions in respect to confinement of a large bath of molten zinc against escape. A further problem was the accommodation of expansion, under air-seal conditions, of a commensurately large arch capable of sustaining the relatively high temperatures involved.

To meet these requirements, the later design of our commercial furnaces at East Chicago was predicated upon the provision of a monolithic hearth construction arranged within a steel shell to confine the molten zinc against escape and loss. Above the hearth, the arch was sprung from skewbacks along the side walls longitudinally of the furnace whereby widthwise expansion of the arch could bow it without impairing the air-tight seals provided at the skewbacks. At the ends of the furnace, the arch extended into pockets or recesses of the end walls which in turn were filled with an elastic or yieldable cement capable of maintaining an air seal while allowing the expansion movements of the arch. Continued operations over a number of years have

proven these principles to be effective and reliable.

Commercial Muffle Furnace

The first commercial unit, producing 5 to 7 tons of zinc oxide per day, was equipped with a vertical riser. This brick riser received zinc vapors from the vaporizing chamber and provided for contact of zinc vapor and air to produce zinc oxide. The zinc oxide was conveyed through a steel duct into a baghouse.

In the operation of the first commercial furnace, the die cast scrap was first

melted in kettles (heated by waste heat) to facilitate removal of unmeltables. These kettles were located in a manner that permitted the molten metal from the kettles to overflow into a sealed opening leading into the vaporizing unit. This practice was not satisfactory because of short kettle life.

Later furnaces embodied melting units consisting of a welded steel shell lined with fire brick to enable melting of the scrap continuously on a molten bath. The die cast scrap was charged onto this molten bath. This proved to be more efficient than kettle melting providing the temperature was adequately controlled.

The melting unit now in use consists

of a sloping hearth inclined toward a central point, which discharges into a trough to the vaporizing unit. With controlled melting unit temperatures, the oxidation of zinc is maintained at a minimum. The results obtained with this melting unit are shown in Table 3.

Muffle Furnace

Assembly drawing Fig 2 and sectional views (Fig 4, 5 and 6) along planes as indicated in the plan as shown in Fig 3 may be helpful in a more detailed study of the furnace design. The letters apply to Fig 1 to 6 inclusive.

- A—Melting Unit
- B—Combustion Chamber
- C—Vaporizing Chamber
- D—Riser
- D2—Condenser

The furnace is fired by oil burners at *E* into the combustion chamber *B* which connects through duct *F* with melting unit *A* and combustion gases are vented through stack *G*. The flow of metal through the furnace is counter-current to the flow of gases. The zinc-bearing material is charged through door *H* (not shown) onto the melting

unit hearth *I* which is considerably above and to one side of the bottom of vaporizing chamber *C*. The molten charge drains from the hearth *I* of the melting unit which is pitched toward the center, through a duct entering the vaporizing chamber at point marked *J*. Means for drossing are provided between hearth *I* and outlet *J*. Unmeltables, such as iron inserts, and the like, are raked from the hearth of the melting unit through door *H2*. It will be noted that the combustion chamber *B* is separated from the vaporizing chamber *C* by a comparatively thin arch *K* to expedite the flow of heat from the combustion chamber into the vaporizing chamber. This arch is made up of standard commercial sizes of carborundum blocks. The arch extends into recesses of the end walls which are filled with an elastic material, forming a seal, and providing for expansion.

Under the proper conditions of temperature and pressure, zinc vapors are produced in chamber *C* which flow through opening *L* in the vaporizing chamber into the riser *D*. These vapors may be burned to zinc oxide as they escape from riser *D* through opening *M* to a zinc oxide collector. This assumes that opening *N* is closed. If it is desired to condense the vapors as metallic zinc, *N* is opened permitting the vapors to enter the condenser *D2*. The condenser may be laid up of carborundum brick which aids in condensing the zinc vapors to metallic zinc due to its high heat conductivity. Pressure, if it becomes excessive, is relieved by ball *O* resting on an opening into the condenser. Zinc wells marked *P* are used for tapping condensed metal.

Vaporizing chamber, condensers and zinc wells are all encased in a steel shell marked *R* which rests on supporting I-beams. The arch and side walls of combustion chamber *B* are constructed of a special high grade refractory. An insulating arch *S* covers the combustion chamber. Referring to the front of the vaporizing chamber *C* beneath the oil burner *E* it will be noted that the pan is first lined with a layer of fire brick, upon which is placed refractory concrete, designed to tighten the furnace against the flow of metallic zinc through brickwork *T*. The inverted arch and side walls of the vaporizing chamber *C* are constructed of high quality fire brick. The bottom arch of vaporizing chamber *C* pitches slightly to one end to assist in tapping metal from this chamber. Opening *Q* allows for atmospheric cooling of the furnace bottom

FIG 3—Plan of muffle furnace showing sections.

and provides for inspection of the bottom of the furnace pan.

Metallic Zinc is produced in the Muffle furnace by closing the opening *M*, used in producing oxide and open-communicating door *N* connecting condensers *D* and *D2*. Drains to zinc wells *P-P* are also opened.

This type of furnace construction provided for: Prevention of leakage of molten zinc by means of a monolithic hearth within a steel shell. Escape of vapors and infiltration of air by a tight arch fully sealed throughout its length and breadth and at the points where the arch joined the furnace. Pressure build up within the vaporizing chamber to permit the desired flow of zinc vapor to the riser and condenser. (Fig 7.)

Operating Procedure

The furnace is preheated with a gas flame, gradually raising the temperature to 1600°F. The oil burners are then started and the temperature of the combustion chamber elevated to 2400°F. Preheating requires about ten days.

Charging of metal is started at 2400°F and the production of zinc vapor begins almost at once. Charging is continued at as rapid a rate as possible until a depth of 5½ in. of metal has accumulated in the vaporizing unit.

This accumulation of metal in the bath is exclusive of the metal vaporized during this period. Charging of die cast metal continues at a rate that will increase the depth of the metal in the vaporizing chamber about one inch for each 24 hr of operation until a total depth of 10 in. of metal is reached. This generally requires from six to ten days, depending on the zinc content of the metal charged. Where a high purity zinc is charged exclusively, the cycle may be extended to as much as 60 days without removal of residue metal.

Conditions which determine the end of the cycle are: The rate of zinc vapor production for economical operation of the furnace, a low zinc content in the residue metal, as tapped from the furnace, and a lead content low enough to meet the requirements of the particular zinc oxide being produced.

The cycle is ended by tapping residue metal from the vaporizing chamber, emptying it as far as possible. This metal is drained through a tap, not shown, into cast iron molds. The temperature of the furnace is held constant while it is being drained.

Furnaces have been operated for 72 cycles such as described above. This represents a continuous operation of approximately two years. The economical life of the furnace is determined by the heat transfer efficiency of the carborundum arch.

FIG 4—Muffle furnace section on line A-A.

The rate of heat transfer is reduced by: Accretions of zinc oxide which accumulate beneath the carborundum arch, an accumulation of slag on top of the arch and a gradual change in the composition of the arch.

Major furnace repairs are required every two years.

Quality of Zinc Oxide

After the initial 20 ft muffle furnace was constructed and placed in operation a gradual improvement became apparent in the color and uniformity of the zinc oxide produced. Many changes in the furnace design improved the quality. The furnace, as now developed, can produce a wide range of zinc oxides including all grades of French Process zinc oxide and with minor modifications has produced acicular zinc oxides. Representative specifications for the French Process zinc oxides that are produced are shown in Table 4.

Production of Zinc

Of the various types of risers tried at East Chicago, several of them indicated the possibility that zinc metal could readily be produced from the muffle furnace. The relative position of the riser with respect to the molten bath of metal in the vaporizing unit seemed ideal to exclude or at least reduce contamination of the zinc metal by copper, aluminum and tin.

A simple design of riser was developed to permit zinc vapors condensed in the risers to be removed through a

trapped opening into a zinc well from which the zinc metal could be removed at convenient intervals. A further development of this idea led to the design of a suitable condenser made of carborundum brick that would permit complete production of zinc metal from all of the vapors leaving the vaporizing units. For the purpose of controlling the rate of zinc condensation, by varying the heat loss, hinged steel frame doors lined with insulation brick were attached to the exterior of the condenser.

Zinc Produced from Secondary Metal

With this type of riser on the furnace, the distillation of zinc from secondary metals became a commercial possibility because the zinc produced in test runs was Prime Western, Brass Special or Intermediate grade. The results of such an experimental run are given in Table 5. In this run die cast slabs and die cast scrap were used as the source of zinc.

FIG 5—Melting unit section on line B-B.

Distillation of Prime Western Zinc

It was recognized that these furnaces could be used for redistillation of impure zinc into higher purity zinc. Results of a test made to determine the efficiency of the redistillation of Prime Western Zinc into higher purity zinc are shown in Table 6.

Table 6 . . . Redistillation of Prime Western Zinc into Higher Purity Zinc

| | Lb | Grade Zinc | Pct of Metal Charged |
|-----------------------|---------|---------------|----------------------|
| Charged..... | 300,095 | Prime Western | 100.0 |
| Metal Production..... | 269,554 | Intermediate | 89.8 |
| | 3,280 | Brass Special | 1.1 |

Distillation of High Grade Zinc

An experiment was conducted to determine the extent and economics of reducing the lead content of electrolytic high grade zinc in a muffle furnace.

Table 7 summarizes the information obtained.

Table 7 . . . Reduction of Lead Content of Electrolytic High Grade Zinc in Muffle Furnace

| | Pct Lead | Lb | Pct of Metal Charged |
|-------------------------------|----------|---------|----------------------|
| High Grade Zinc Charged..... | 0.0081 | 366,085 | |
| Condensed Metal Produced..... | 0.0032 | 302,225 | |
| Residue Metal..... | | 17,070 | |
| Metal in Process..... | | 44,800 | |
| Recovery..... | | | 99.46 |

In this test the average production of metal per 24 hr was 29,257 lb. The oil consumption averaged 800 gal per 24 hr.

By-products

Several important by-products are produced in the conversion of die cast and zinc scrap into zinc or zinc oxide.

UNMELTABLES

The first by-product obtained is in the form of iron inserts or foreign material that is frequently associated with many forms of zinc scrap. The general term "unmeltables" is used to describe this form of by-product.

The following analysis as shown in Table 8 indicates the metals present in the unmeltables in addition to iron and zinc.

Table 8 . . . Metals in Unmeltables in Addition to Iron and Zinc

| Pb | Cu | Sn | Ni | Cr | Al |
|------|------|------|------|------|------|
| 4.39 | 3.61 | 0.80 | 0.36 | 0.11 | 10.0 |

MUFFLE DROSS

As the scrap is melted in the melting unit or in a kettle some of the zinc is oxidized. The partially oxidized zinc (muffle dross) is screened from the unmeltables and set aside for treatment or sale to zinc smelters. A representative analysis of muffle dross is shown in Table 9.

Table 9 . . . Analysis of Muffle Dross

| Zn | Pb | Cu | Sn | Fe | Al | Insol. |
|------|-----|-----|-----|-----|------|--------|
| 69.7 | 5.1 | 4.0 | 2.3 | 8.5 | 10.0 | 0.4 |

RESIDUE METAL

The distillation of zinc from die cast metal concentrates the other metals (principally aluminum and copper) present in the original alloy. A representative analysis of residue metal is shown in Table 10.

Table 10 . . . Analysis of Residue Metal

| Al | Cu | Zn | Sn | Fe | Pb |
|------|------|-----|-----|-----|-----|
| 33.3 | 51.9 | 8.0 | 2.9 | 3.1 | 0.4 |

RECOVERY OF TIN-LEAD ALLOY FROM RESIDUE METAL

The residue metal is tapped from the furnace at between 5 and 10 per cent zinc content. This metal is remelted in a special liquation furnace in such a manner as to form a two-layer system. The lower layer which consists of a molten lead-tin alloy containing a small

FIG 7—No. 4 muffle furnace.

amount of zinc is tapped from beneath the solid upper layer. This crude lead-tin alloy is refined by removal of the zinc with chlorine and the final refining with caustic soda. It is used as a lead-tin alloy.

RECOVERY OF ALUMINUM FROM RESIDUE METAL

A number of studies were made of the best means of utilizing the aluminum and copper alloy which was left after the zinc, lead and tin had been removed from the residue metal. It was recognized that if the aluminum-copper alloy was freed of undesirable impurities it should be attractive to the die cast producer who could use it by adding electrolytic zinc to produce a high grade die casting alloy.

Extensive experiments were made to electrolyze residue metal in a fused salt cell. The cathode deposits were a high grade aluminum. As the aluminum was removed from the molten electrolyte the copper content of the residue metal increased and reached the point where the operating difficulties of such elec-

trolysis became more and more complex and unattractive. The conclusion was reached that this sort of treatment to recover aluminum from residue metal might prove attractive if low cost power were available.

RECOVERY OF COPPER FROM RESIDUE METAL

The copper content of the residue metal is high enough to interest the copper smelters in its utilization. It has been treated in copper reverberatories along with the melting of scrap copper to produce electrolytic copper. In this treatment the aluminum values are lost in the reverberatory slag.

The residue metal can also be treated in copper converters where the aluminum is oxidized to Al_2O_3 and discarded in the converter slag. Great care, however, is necessary in this type of operation because the reaction between the copper sulphides and metallic aluminum is vigorously exothermic under certain conditions. Large quantities of this residue metal have been sold to manufacturers who find this alloy

useful for their needs. It is obviously a secondary aluminum alloy that contains attractive values for many alloy specifications.

Acknowledgment

Acknowledgment is given to Messrs. George Anderson and R. S. Olsen for their early experimental contributions in the development of the muffle furnace. Appreciation is expressed for the valuable cooperation and assistance of Messrs. P. S. Toney, W. P. Ruemmler and E. F. Weaver of the East Chicago staff in the preparation of the manuscript.

The Effect of Orientation Difference on Grain Boundary Energies

C. G. DUNN,* Member AIME, and F. LIONETTI†

THE energy associated with grain boundaries in polycrystalline aggregates is believed to play a major role in grain growth processes and, when growth ceases, to determine the final equilibrium grain boundary angles. Further, the energy of grain boundaries of recrystallization nuclei is a factor in nucleation processes. It is important to know, therefore, how the energy per unit area of a grain boundary, that is, the grain boundary surface tension γ , depends on the difference in orientation of the two lattices of the grains producing the boundary. Although the problem is important, surprisingly little has been done toward a quantitative evaluation of the effect of orientation difference on grain boundary energies.

C. S. Smith¹ recently has discussed this problem and in addition to showing effects of orientation difference on equilibrium angles has shown a variety of interesting effects of surface tension on the appearance of microstructures. Fig 1 and the following relations expressed in Eq 1, which connect equilibrium grain boundary angles and surface tensions, illustrate equilibrium conditions which are believed to hold true in metals.

$$\frac{\gamma_{12}}{\sin \theta_3} = \frac{\gamma_{23}}{\sin \theta_1} = \frac{\gamma_{13}}{\sin \theta_2} \quad [1]$$

Clearly any two of these surface tensions can be expressed in terms of the third when the equilibrium angles θ_1 , θ_2 , and θ_3 are known.

Applied to the present problem for solid state equilibrium of three grains, the angles θ_1 , θ_2 and θ_3 must be measured in a plane perpendicular to the line of junction of the three grains. Normally a direct determination of these angles

from random microsections is impossible. Consequently Harker and Parker² and Smith¹ (except for some measurements on flat specimens) resorted to a statistical method to determine equilibrium grain boundary angles. Smith reported that grain boundaries meet the surface of a piece of metal nearly perpendicularly. He reported also, in connection with direct angle measurements on flat specimens with grains extending through the thickness, that angles varied appreciably from 120° and concluded that there was a measurable effect of orientation difference on surface tension.

Another direct way of determining equilibrium angles and a method adaptable to studying particular configurations, recently suggested by Dunn,³ is to use a three-grain flat specimen with orientations of grains so chosen that the junction line of the three grains will be straight throughout the thickness and perpendicular to the surface of the specimen. Choice of orientations is possible when individual grains of each group can be grown to predetermined orientations through the reorienting and growth of "seed crystals" as described.³ Not only is it possible,

for example, to have grains with the same crystallographic plane in the plane of the specimen, but a given orientation difference between two grains can be made a common factor to an unlimited number of three-grain groups while a series of orientation differences is investigated. Any effect of anisotropy of gas-solid surface tension due to grain orientation should be minimized by having all grains oriented the same with regard to crystallographic plane in the plane of the specimen.

Another feature of the three-grain group is the notched grain boundaries as shown in Fig 2 for one specimen (S4). The notches serve to anchor the end positions of the grain boundaries (especially at high temperatures) while the central and junction point of the grains moves toward an equilibrium position. Final equilibrium should produce straight grain boundaries if the notches are very narrow and if changes in orientation* of the grain boundary do not alter the surface tension.† If one assumes the straight line condition and no change of surface tension with small changes in grain boundary orientation and finds the equilibrium configuration by a minimization of the grain boundary energy, one obtains the relations given in Eq 1.

The approach to straight line boundaries or to minimum energy configurations in specimens containing large grains, such as those used in the present investigation, may be very slow compared with the approach to equilibrium conditions for the grain boundary angles. It may be desirable, as proved to be the case in the present investiga-

* Change in orientation of a grain boundary is not to be confused with difference in orientation between two grains.

† An effect of grain boundary orientation must exist for crystal orientations near the twinned position. A measurable effect may also exist for other crystal orientations. (See Ref. 1.)

FIG 1—Interface equilibrium between three immiscible liquids and mechanical analogy with triangle of forces. (After Smith.)

tion, to observe relatively small changes in the boundaries near the junction point of the three grains rather than wait for large changes to occur in the grain boundaries prior to making accurate angle measurements.

In the present report a series of groups, each of three grains with the (110) plane in the plane of the specimen, are investigated. The difference in orientation between two grains i and j , with grain boundary surface tension γ_{ij} , is given in terms of an angle Δ_{ij} , which is the angle separating the [001] directions of the two grains. Each three-grain specimen, therefore, has three values of surface tension (γ_{12} , γ_{13} , γ_{23}) corresponding to the three grain boundaries where the differences in orientation of the grains are Δ_{12} , Δ_{13} and Δ_{23} respectively. Each three-grain group has one boundary where the difference in orientation of the grains is 15° , a value chosen somewhat arbi-

trarily. The purpose of the common value of Δ is to permit the calculation of surface tensions in terms of one surface tension (γ_c) which is assumed not to vary much with grain boundary orientation. Values of Δ_{ij} cover the range 5° to 90° .

If orientation of the grain boundary has little effect on the surface tension γ , then γ can be expressed as a simple function of Δ , the difference in orientation. However, even if the orientation of the grain boundary should prove to have little effect in general, the existence of twins with definite composition planes alone indicates an effect of grain boundary orientation when two lattices are near a twinned relation. McKeehan⁴ and Preston⁵ from considerations of the distances between atoms in a lattice and the distance between atoms at a twin boundary, showed that certain composition planes resulted in lower stress or lower

boundary energy. On the basis of measured grain boundary angles, Smith¹ reported that the surface tension for a twin boundary in face-centered cubic metals must be relatively small.

In the present investigation no attempt was made to control the orientation of grain boundaries during the preparation of three-grain groups.

PREPARATION OF SPECIMENS

Silicon ferrite with about 3.5 pct silicon was selected for the investigation because the technique of growing three-grain specimens with each grain in a definite orientation had been previously developed. Furthermore, silicon ferrite remains a single phase even at high temperatures; so temperatures of 1300 – 1400°C , or near the melting point if desired, could be used to effect a more rapid approach to equilibrium.

FIG 3—Stereographic projection of the {100} poles of the three grains in S2.

In the laboratory cold rolled strips of silicon steel of commercial grade were made in the form of sheets 0.025 in. thick. These had the property of supporting exaggerated grain growth. Upon lowering pieces of this material into a furnace with a high temperature gradient, large grains formed in the hot end. Two of these grains about one inch apart in each sample were then X rayed and analyzed for orientations. From the stereographic projection of the orientation of each grain, the two angle rotations necessary to bring a (110) plane into the plane of the specimen and a [001] direction into a pre-determined azimuthal position could be read easily from a Wulff net. A small machine with angular scales was used to reorient each crystal, the neck part of the specimen (see Ref. 3 for illustration) being held at red heat during this operation to permit easy plastic flow of the metal.

Each specimen with its two re-oriented seed crystals was then fed into a furnace with a high temperature gradient in order to grow two grains in one end. The speed of a specimen generally was about $\frac{1}{2}$ cm per hr. In a similar manner, a third crystal was seeded, analyzed, reoriented, and grown from the opposite end. Eleven specimens were made, all but S8 by the exaggerated grain growth method. In the case of S8 where one Δ value reached 90°, a strain-anneal type of transformation was used. To facilitate identification, each sample was shaped differently. Also it will be noted that the three initial grain boundary angles obtained in specimens made in the manner previously described, if measured very roughly, will be near 90, 90, and 180° respectively (see Fig 2).

After preparation, the orientations of all grains were determined. Fig 3, which is illustrative of all specimens, shows a stereographic projection of the {100} poles of the three grains 1, 2, and 3 of S2. Tilt of the (110) plane did not exceed 2°. In general since the (110) planes were quite close to the plane of the specimen (within 3°), determining the [001] direction of each grain sufficed for a simple calculation of each orientation difference Δ . The plotting of stereographic projections, as shown in Fig 3, was not necessary since a direct reading analyzer could be used to find the direction of the zone axis of the [001] zone of Laue spots which were present in each Laue photograph. The tilt of the (110) plane could also be read directly from the film.

ANNEALING

On the assumption that well defined equilibrium angles with grain boundaries lacking or nearly lacking in curvature over appreciable distances could be obtained, it was decided to anneal each sample a number of times and observe the approach toward equilibrium. Temperatures near 1300 or 1400°C were considered necessary, and higher temperatures were avoided during long anneals since a failure of the furnace controls while the furnace was unattended could have been disastrous with samples too near the melting point. Furthermore, the higher temperatures favored the sticking of the specimens to supporting plates or surrounding material and this was undesirable. To prevent sticking at high temperatures, samples were separated from supporting and surrounding pieces of silicon iron by a thin layer of alumina powder.

A preliminary anneal of 48 hr at 1350°C with an atmosphere of pure

dry hydrogen disclosed a serious de-siliconization effect for some thin sheets of silicon iron and S3, S4, S5, and S7. Sufficient silicon was removed from the thin sheets of silicon iron to allow them to transform completely by a phase change. S7 and S4 had transformed sufficiently to require replacements. S9, S10 and S11, therefore, were immediately made. S3 and S5 showed some transformation along the edges but this was much less than the transformation in S4, a photograph of which is shown in Fig 4. The photographs of S4, shown before and after the 1350°C hydrogen anneal in Fig 2 and 4 respectively, clearly indicate a change in the grain boundaries near the common grain boundary point.

All samples were then annealed for about 70 hr at 1150°C in pure dry hydrogen. Although grain boundary changes were observable, it appeared expedient to anneal next in dry argon for 48 hr at 1300°C and then obtain some measure of the grain boundary angles. Measurements after the anneal were made at a magnification of 30 diam. Accuracy in the measurements proved difficult to obtain. Additional straightening of the boundaries, however, was anticipated; so the samples were given another anneal of 48 hr, this time at 1350°C in dry argon. Measurements on a number of specimens, especially S5, indicated a stabilizing condition of the angles. A comparison of photographs taken at different times also indicated a marked dropping off of grain boundary movement. A final anneal of 48 hr at 1400°C in an atmosphere of argon was then given the samples. Only minor further changes in grain boundaries occurred in this anneal. Long annealing, therefore, at these high temperatures had not produced the macrochanges sought for as an aid to the quantitative measure of the approach toward equilibrium

conditions. The angle measurements in some cases agreed well with previous ones; in three cases it was clear that the specimens would first have to be mounted and polished metallographically so that a higher magnification could be used. Angles could be measured fairly accurately on some of the samples in the "as annealed" condition because the grain boundaries were clearly visible.

Experimental Results

STRUCTURE

Photographs of S4 shown in Fig 2 and 4 have already been discussed in connection with the changes produced by the removal of silicon.

Fig 5, showing a series of photographs at slightly less than double magnification of S5, illustrates well the early visible changes and the later stabilization of the boundary positions.

Photographs in Fig 6 likewise show the changes that occurred in S11. From the standpoint of macrochanges which were visible at no magnification, this specimen was the poorest of the

nine used in the determination of grain boundary angles. Only slightly better in this respect was S9. Photographs of S9 are shown in Fig 7, one at about 2 diam magnifications, the other two at 5 diam. These photographs clearly show that grain boundary movement occurred in the 1150°C hydrogen anneal and also in subsequent anneals.

As mentioned previously three of the

samples showed poor macroboundaries. These samples (S1, S9, and S3) were polished and the boundaries observed at 400 diam magnification. Fig 8 shows a photograph of the boundaries of S1, the specimen with the smallest differences in orientation. It is interesting to note that the boundary associated with largest difference in orientation, which stands out sharply in the photograph, is opposite an acute angle. S9,

 FIG 9 (below)—Micrograph of S9 after annealing. Nital etch. $\times 400$

which has already been discussed in connection with Fig 7, had one grain boundary that continuously curved near the common grain boundary point. This feature is apparent in the photograph shown in Fig 9. Angle measurements were made at 30 diam and then again from the photographic plate taken at 400 diam. One angle, defined by the straight grain boundaries, checked well in these two measurements. Readings from the plate were sufficiently accurate to permit checking the angles to within one degree. The angle measurements of S3 made at a magnification of 400 diam checked quite well with those taken at 30 diam.

Sections were made through a number of grain boundaries to determine how the boundaries passed through the specimen. Although the boundaries in general were close to the perpendicular position, there were some cases of departure from perpendicularity by as much as 5 to 10 degrees.

EQUILIBRIUM ANGLES AND CALCULATED RELATIVE SURFACE TENSIONS

Data for the nine specimens measured are given in Table 1. Following

the columns of orientation differences under Δ_{12} , Δ_{23} , Δ_{13} are the gross initial grain boundary angles listed under initial angles. Referring to Fig 1 it will be noted that θ_3 is the angle opposite the grain boundary formed by grains 1 and 2 where the surface tension is γ_{12} . This is also the boundary where the orientation difference is Δ_{12} . The columns giving the second set of θ values are the final measured angles—the equilibrium angles. Using these angles and Eq 1, relative values of γ were calculated. Results appear in the table under the column headed "calculated surface tensions." A plot of γ against Δ indicated that γ was changing at an

FIG 10—Plot showing variation of relative surface tension γ/γ_c (corrected) with difference in orientation Δ .

appreciable rate with Δ for values of Δ near 15° . Consequently γ for Δ equal to 16.5° , for example, should be slightly larger than γ for Δ equal to 15° , the approximate common value. From the shape of the curve a small correction could be made so that γ_c would apply only to Δ equal to 15° . This correction proved to be less than 4 pct in general. The same percentage change as that made in γ near 15° was also made for the remaining two γ values of each specimen. Results are listed under "corrected surface tensions." A plot of γ/γ_c versus Δ , using the corrected values given in the table, is shown in Fig 10.

Discussion of Results

The relationship between surface tension γ and orientation difference Δ shown by the curve in Fig 10 has three rather striking features: 1. A rapid decrease of surface tension with decreasing Δ for values of Δ less than 15° ; 2. A maximum surface tension for orientation differences in the range of 20 to 30° ; 3. A dip in the curve for orientation differences near 70° .

In regard to the first feature, one would expect some type of approach toward zero surface tension with decreasing Δ since the boundary must vanish at Δ equal to zero. The second point will be discussed later. In the case of the third point, however, one can speculate somewhat on the twin relation. If the boundary between

grains 1 and 3 had been grown near a (112) plane, then approximate artificial (112) twins (grains 1 and 3) might have developed on annealing and a marked dip in the curve expected from the lower energy of a (112) twin boundary. Actually the 1-3 boundary in S10 and in S11 was grown much nearer a (111) plane, but the final configuration not only departed appreciably from the (111) plane but was different in the two specimens. The observed dip in the curve as well as the disagreement for S10 and S11 may reasonably be connected with an effect associated with the twin orientation even though the boundary is removed from a {112} plane. In the particular configuration involving two grains 1 and 3 with (110) planes in the plane of the specimen but differing in orientation by $70^\circ 32'$, the more complete nature of this effect could be investigated by varying the orientation of the 1-3 boundary during the formation of each three-grain group.

S5 and S9, with orientations far removed from any twin position, actually illustrate the variation of grain boundary orientation in the initial samples for a constant set of Δ values. Referring to Table 1, the Δ values for both these specimens are seen to be roughly 15° , 25° , and 40° . The initial gross angles, however, are different except for angle θ_3 which was 90° for both specimens. (Other grain boundary directions and initial gross angles could have been formed by varying the direction of grain growth in each specimen.)

The purpose of making two angles θ_1 different in S5 and S9 was to have θ_1 increase from 90° in S5 and decrease in S9 (if the equilibrium angle was between these two values) until the two reached a common value, or the equilibrium angle. A converse relation would, of course, hold for θ_2 . Lack of the anticipated large grain boundary movements prevented the measuring of the approach toward equilibrium in these samples. As far as angles measured on a small scale are concerned, which finally had to be done, in general the initial gross angles probably have little significance.

Lack of agreement for the final angles for S5 and S9, although possibly due in part to an effect of grain boundary orientation, may be due to failure to reach equilibrium. This view may seem unreasonable at first since long anneals at high temperatures were used in an attempt to reach equilibrium. There is one factor, however, which tends to prevent the reaching of equilibrium conditions as required in the application of Eq 1. Inclusions in a metal exert a constraining force to grain boundary movement, as Smith¹ (see Ref. 24) pointed out in connection with the work of Zener. It was further indicated that, under certain conditions, inclusions should completely stop boundary movement.

With regard to a maximum point on the surface tension curve, it can only be said that one should occur between zero and 70° if there is a marked dropping off of surface tension near 70° .

Considering all nine specimens, and the possibility of some effect of grain boundary orientation, the general consistency of the trend of variation of γ with Δ (especially in the range 15 to 45° where more points have been obtained) indicates that the effect of inclusions in general probably was not too serious. Nevertheless, it would be very desirable to use material of the highest possible purity to insure the attainment of better equilibrium conditions.

Although inclusions may stop a strongly curved grain boundary from moving further, the grain boundary orientation effect may also lead to a curved surface in order to produce a minimum energy configuration (this was also discussed by Smith¹). With reference to the application of the present technique, consider a two-grain specimen with the grain boundary ends anchored and having grains with the same crystallographic plane in the plane of the sheet. If the grain boundary surface tension γ is high for the straight grain boundary compared to other directions, then a curved boundary could correspond to lower energy. We have here the case of minimizing the total energy obtained from the product of boundary area and surface tension, which may be expressed as follows:

$$\text{Total grain boundary energy} = \int \sigma \gamma d\sigma$$

where $d\sigma$ is an element of surface area and the integration is carried out over the entire boundary surface σ . The surface tension γ , of course, is considered to vary from point to point on the surface with orientation of the surface element $d\sigma$. A minimization of grain boundary energy would be valid only when relative sizes of the two grains produce no additional effect on total (internal plus surface) energy.

In any case, the nature of variation of surface tension with grain boundary orientation should be determined in order to obtain a clearer picture of the effect of orientation difference on surface tension. In the case of three-grain groups with common (110) planes, the curve for small values of Δ should be investigated more completely. Finally, three-grain groups with other crystallographic planes in the plane of the specimen should also be investigated and the results of surface tension measurements put on a common relative basis with those of the (110) series.

If relative surface tensions vary with particular orientation differences, as Fig 10 would indicate is actually the case, then some fundamental relationships may be found between surface tension data and recrystallization data involving orientation relationships. In this connection it is interesting to point out some possible correlations, using the shape of the curve in Fig 10 and published facts on recrystallization in silicon ferrite. Dunn⁶ reported a rapid rise in the number of recrystallization nuclei with orientation difference for Δ in the range 10 to 20° and no nuclei with small Δ values. Referring to Fig 10 we note a similar rapid rise in the surface tension starting with small values of Δ . Secondly, the data on recrystallization nuclei show a maximum number of nuclei for Δ equal to approximately 25° with nuclei also having a {110} plane common with the original deformed grain (see Fig 8 of Ref. 6 for curve). The curve of surface tension versus Δ (Fig 10) has a maximum in this same region of orientation difference. However, until other crystallographic relationships are investigated and all values of surface tension are compared, the coincidence of maximum points probably should not be considered too significant. On the other hand some relationships involving either the ease of forming a nucleus or the ability of a nucleus to grow more rapidly in a deformed single crystal because of special orientation relationships is expected.

Experimental data on surface tensions are needed, of course, for application to the problem of grain growth following recrystallization, especially under conditions where recrystallization textures depart from random textures. Further, a strong texture material should have lower total grain boundary energy per unit volume than a random texture material provided both materials have the same grain size and provided the initial part of the curve of relative surface tension does not rise too rapidly to some approximate constant value. A curve of relative surface tension having the form shown in Fig 10 would indicate an appreciable dependence of energy on texture.

Summary

1. Eleven flat specimens of silicon ferrite each composed of three grains were prepared having (110) planes in

the plane of the samples. The common grain boundary point of the three grains was centrally located.

2. Each sample was annealed for long periods of time in the temperature range 1300–1400°C until further change in grain boundaries seemed unlikely and equilibrium angles apparently had been obtained.

3. After annealing, the grain boundary angles were measured and the relative surface tensions calculated. Since each group of grains contained a similar type of boundary (one where the grains had a 15° difference in orientation) it was possible to calculate all surface tensions on a common basis.

4. A curve was obtained showing the variation of relative surface tension (relative energy in the grain boundary per unit area) with difference in crystal orientation.

Acknowledgments

The authors wish to express their appreciation to Drs. J. H. Hollomon and J. C. Fisher for valuable discussions on the problem of measuring surface tensions. Thanks are also extended to Mr. E. F. Welter for aid in the preparation of specimens and the making of X-ray photograms and to Miss Mary Burdette for the micrographs appearing in the manuscript.

Solubility Relationships of the Refractory Monocarbides

JOHN T. NORTON* Member AIME and A. L. MOWRY*

THE monocarbides of the A subgroup elements in the fourth and fifth group of the periodic table in addition to being hard and refractory are of special interest in that they are isomorphous in crystalline structure. They are cubic with a sodium chloride type structure in which the metal atoms are essentially close packed in a face-centered cubic arrangement with the carbon atoms placed in the interstices between.

Interstitial structures of this close packed type were first investigated systematically by Hägg¹ and he gave the rule for their formation, stating that the radius ratio of the nonmetal to the metal atom should not exceed the value of 0.59. The carbides of interest are those of titanium and zirconium of the fourth group and vanadium, columbium and tantalum of the fifth group. Table I shows the radius ratio using the Goldschmidt radii for 12 coordination for the metal atoms and the diamond radius for the carbon atom.

It will be noted that while there is considerable variation in the size of the metal atom, in all cases the ratio is smaller than the limit of 0.59 placed by Hägg.

It has been known for some time that these cubic carbides are soluble in one another, at least to some extent or, in other words, the metal atoms can be replaced, one by another without destroying the stability of the structure. Since the stability of these close packed interstitial substances appears to depend more upon geometry than upon the exact chemical nature of the atoms involved, it is of interest to examine the possibilities of replacement in these carbides in some detail.

Hume-Rothery² has pointed out the importance of the difference in size of solute and solvent atom as a factor in limiting the solubility in simple binary

Table 1 . . . Radius Ratio for Metal Atoms and Diamond Radius for Carbon Atom

| Metal | Radius, Metal, A.U. | Radius, Carbon, A.U. | Radius Ratio |
|-------|---------------------|----------------------|--------------|
| V | 1.35 | 0.76 | 0.56 |
| Ti | 1.46 | 0.76 | 0.52 |
| Cb | 1.47 | 0.76 | 0.52 |
| Ta | 1.47 | 0.76 | 0.52 |
| Zr | 1.60 | 0.76 | 0.48 |

solid solutions. Largely on an empirical basis, he states that if the difference in size between solvent and solute atom is more than 14-15 pct of the solvent atom, the range of solubility is very restricted. The atom size was based on the distance of closest approach in the elements involved. While there is some question as to how one should calculate the size of the metal atom in the carbide structures, reference to Table 1 will show that zirconium is the largest and vanadium the smallest of the group and that the difference is about 15 pct. The Ti-Zr difference is about 9 pct and the others are smaller. Thus one would predict that if the size factor controls the solubility, all of the pairs except VC-ZrC would have wide or complete solubility whereas this latter pair is on the border line and might have restricted solubility.

The purpose of the present investi-

gation was to examine the solubility of the several pairs of carbides by heating them together until equilibrium was established and then examining the product by X rays.

Previous Work

Agte³ and his associates prepared various transition metal carbides and determined the melting points of binary mixtures. He concluded from the shapes of the melting point curves that there was extensive solubility in the case of the cubic carbides.

Umanskii⁴ and his colleagues made an investigation of a number of pairs of the cubic carbides, using X rays and plotted lattice parameter vs. composition curves for the systems TaC-TiC, CbC-TiC, TaC-ZrC and CbC-ZrC. All pairs showed a continuous series of solid solutions. The first two pairs gave a linear relation while the latter two showed a negative deviation from Vegard's law.

Kiefer and Nowotny,⁵ in a paper which became available after the present work was well advanced, investigated the binary pairs of the five cubic carbides by means of X rays. Relatively few points were obtained and results indicated that in some cases, at least, equilibrium was not reached at the temperatures used. The results indicated that solubility in the VC-ZrC system was not complete. All of the results of previous investigations indicated the desirability of a more detailed study.

Materials

The raw materials used were monocarbides of titanium, zirconium, vanadium, columbium and tantalum and were the purest which could readily be obtained commercially. Spectrographic qualitative analysis showed that the CbC and TaC contained less than 1 pct

FIG 1—Lattice parameter vs. composition curve for the carbide pairs, CbC-TiC, Cb-VC, TiC-TaC, and VC-TaC.

of other metals. The TiC showed the presence of appreciable amounts of Cr, Fe, Si, V and Zr; the VC contained B, Cr, Fe, M and Si while the ZrC contained appreciable amounts of B, Fe and Ti. All were somewhat deficient in combined carbon content. The results of the investigation were such that the presence of these impurities does not influence the validity of the conclusions.

Experimental Procedure

Heating of the carbide mixtures was carried out in a high frequency vacuum furnace of conventional design, using a graphite crucible. Temperature was measured with a calibrated optical pyrometer sighting through a small tube in the crucible cover directly on the central specimen of the charge. Temperature was maintained by manual control during the heating runs within a limit of $\pm 20^\circ\text{C}$.

The individual carbides were mixed with additional carbon to correct the deficiency and heated in vacuum at 2100°C for 3 hr to recarburize and to volatilize some of the impurities. These carbides were then carefully weighed out and mixed in pairs at 10 molecular pct intervals. The mixing was done in a small stainless steel ball mill using benzene as a dispersing agent. Excess carbon powder was added as well as 1

pct of powdered cobalt to act as a diffusion aid during sintering. After mixing, the powders were pressed into small slugs and sintered.

The sintering was carried out at 2100°C in the vacuum furnace for a period of 3 hr in order to obtain an equilibrium state and then cooled in the furnace. During this treatment practically all of the cobalt was evaporated from the specimens. Equilibrium was judged from the appearance of the X ray diffraction lines which were sharp with well resolved alpha doublets after this treatment. A one hour treatment at temperature appeared to be sufficient in most cases but the longer treatment was used to make certain.

It was not possible to analyze all specimens after sintering but certain specimens selected at random and analyzed chemically for the metal content showed that the compositions as mixed and after sintering, did not differ by more than an amount corresponding to ± 2 molecular pct.

The X ray examination was carried out using radiation from a copper target and a Phragmen type focusing camera which covered the angular range from 45 to 83° . The powder specimens were prepared by crushing the sintered slugs, grinding in a mortar and mounting the fine powder on paper strips with adhesive. Some observa-

tions of relative line intensities were also made with the Norelco recording X ray spectrometer.

The X ray wavelength values used in calibrating the cameras and calculating the lattice constants were as follows:

Copper K beta —1.39217 A. U.

K alpha 1—1.54050 A. U.

K alpha 2—1.54434 A. U.

Thus the lattice constant values are in true Angstrom units. It must be remembered when comparing results with previous work that slightly different values of the wavelengths may have been used in the past.

X ray Results

The structures of the individual carbides were all of the NaCl type with metal atoms at coordinates 0, 0, 0; 0, $\frac{1}{2}$, $\frac{1}{2}$; $\frac{1}{2}$, 0, $\frac{1}{2}$; $\frac{1}{2}$, $\frac{1}{2}$, 0. The carbon atoms undoubtedly are at coordinates 0, 0, $\frac{1}{2}$; 0, $\frac{1}{2}$, 0; $\frac{1}{2}$, 0, 0; $\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$; although no attempt was made to verify this conclusion in the present research.

The lattice parameters of the individual carbides are given in Table 2.

Table 2 . . . Lattice Parameters of Individual Carbides

| CARBIDE PARAMETER IN A.U. | |
|---------------------------|-------------------|
| ZrC | 4.689 ± 0.001 |
| CbC | 4.470 0.001 |
| TaC | 4.457 0.001 |
| TiC | 4.329 0.001 |
| VC | 4.169 0.001 |

FIG 2—Lattice parameter composition curves for the carbide pairs, ZrC-TaC, CbC-ZrC, CbC-TaC, and TiC-ZrC.

A higher precision in the determination of the parameters of the individual carbides is not warranted in view of the small amounts of impurities present.

With the exception of the VC-ZrC series the X ray photographs of all of the other sintered binary pairs showed the presence of only a single phase having the same NaCl structure as the individual carbides but with varying lattice parameters. Fig 1 and 2 show graphically the variation of lattice parameter with composition of the carbides taken in pairs. It will be observed that the values lie on smooth continuous curves which depart only slightly from straight lines indicating uninterrupted series of solid solutions in each case.

The exception is the VC-ZrC system, the results of which are shown in Fig 3. Here all of the intermediate compositions between 10 and 90 molecular pct show two cubic phases of constant parameter having values close to the individual carbides. This indicates very limited solubility.

At the VC end of series, the lattice constants of the smaller cubic phase in the two-phase field is the same as that of VC, within experimental error. A specimen containing 4 molecular pct ZrC is definitely two-phase. Thus the solubility of ZrC in VC is certainly less than 4 pct and probably less than 1 pct.

At the ZrC end of the series, a defi-

nite but small solubility is indicated since in the two-phase region, the larger cubic phase has a parameter of 4.674 A. U. while that of ZrC is 4.689 A. U. An alloy containing 6 pct VC is two phase. If Vegard's law applies, the solubility would be 4 pct VC. One may conclude that the actual value of solubility of VC in ZrC at 2100°C is approximately 5 molecular pct. Carbides of higher purity would be necessary to obtain a more precise value.

Discussion of Results

The experimental results on the several pairs of carbides show clearly the limit placed on solubility by the size factor. A quantitative expression of the size factor depends upon the method of defining the atom size. One method is to employ the Goldschmidt atomic diameters, obtained from the distance of closest approach in the elements and corrected to a coordination number of 12. Another method is to assume that the metal and carbon atoms are in contact along the cube edge and that the carbon atom has a diameter which is constant for all of the carbides at a value equal to that in the diamond. The metal atom diameter is then calculated from the measured lattice parameter. Still a third method is to calculate the metal-to-metal atom distance in the carbide

based on the measured lattice parameter. Table 3 shows a comparison of these methods of calculation.

Table 3 . . . Atomic Diameters of Metal Atoms in A.U.

| Metal | D ₁ | D ₂ | D ₃ |
|-------|----------------|----------------|----------------|
| V | 2.69 | 2.66 | 2.95 |
| Ti | 2.93 | 2.82 | 3.06 |
| Ta | 2.94 | 2.95 | 3.15 |
| Cb | 2.94 | 2.96 | 3.16 |
| Zr | 3.19 | 3.18 | 3.31 |

D₁ = Diameter from element corrected to coordination number of 12.

D₂ = Diameter from carbide assuming carbon diameter of 1.511 A. U.

D₃ = Distance of closest approach of metal atoms in carbide.

A comparison of these values shows that in the carbides, the metal atoms have closely the same size as in the metals themselves and that in the carbides they are not quite closely packed but are pushed apart slightly by the carbon atoms. The exception is TiC where the diameter of the Ti atom in the carbide is definitely smaller than in the metal. No explanation suggests itself for this fact.

Using the value of D₂ in Table 3 one can calculate the percentage size differences for the several carbide pairs. The results are shown in Table 4.

Thus it can be seen that in this series of solid solutions in which the chemical properties of the elements are very similar but the size factor varies, extended solubility is possible if the

FIG 3—Lattice parameter composition curves for the carbide pair VC-ZrC.

Table 4 . . . Size Difference in Carbide Pairs

| Carbide Pair | Difference in Pct Smaller as Solvent | Difference in Pct Larger as Solvent |
|--------------|--------------------------------------|-------------------------------------|
| VC-ZrC | 21.1 | 16.3 |
| TiC-ZrC | 12.8 | 11.7 |
| VC-CbC | 11.3 | 10.0 |
| VC-TaC | 10.9 | 9.8 |
| TaC-ZrC | 7.8 | 7.2 |
| CbC-ZrC | 7.4 | 6.9 |
| VC-TiC | 6.0 | 5.7 |
| TiC-CbC | 5.0 | 4.7 |
| TiC-TaC | 4.6 | 4.4 |
| TaC-CbC | 0.34 | 0.34 |

difference in size of solute and solvent is 13 pct of the size of the solvent. If this figure increases to 16 pct the solubility is very restricted as in the zirconium-rich end of the VC-ZrC system and is practically zero at 21 pct which is the vanadium-rich end of this same system. This is in good agreement with the rule found for simple binary solid solution alloys.

The lattice parameter composition curves for the binary carbide pairs which form continuous series of solid solutions show slight variations from the linear relation required by Vegard's law. In the systems TiC-VC and CbC-TaC, the line is practically straight. Systems CbC-TiC, CbC-VC, TaC-TiC, TaC-VC and TiC-ZrC show a positive deviation. Systems CbC-ZrC and TaC-ZrC show a negative deviation. The maximum deviation occurs at a composition of about 50 molecular

pct, the maximum positive value being 0.72 pct in the TaC-VC system and the maximum negative value being 0.40 pct in the TaC-ZrC system. At the present, no particular significance can be assigned to these small deviations.

There is no evidence in the sintered solid solution alloys that the distribution of the two kinds of metal atoms on the face-centered cubic lattice is other than random. Calculated and observed X ray line intensities are in good agreement on this basis and no superstructure lines have been observed. It is possible, however, that ordering might be induced by heating for long periods in the temperature range around 1500–1800°C. The system most likely to show ordering would be the TiC-ZrC system since this is the largest size difference for complete solubility. The composition ratios 3–1 and 1–3 should be examined since these compositions are favorable for the face-centered cubic lattice. The difference in atomic number should make it possible to recognize the existence of order in the structure by means of X rays.

The possibility other than ordering is that a solubility gap may exist at temperatures lower than 2100°C. Here again the TiC-ZrC system would be the most likely one. These two points are now under investigation.

Since the solubility of one carbide in another is limited by the change in

lattice energy resulting from the strain produced by the misfit of the atoms, it is interesting to speculate about what would happen in the case of a ternary solid solution. For instance, suppose a mixture of equal parts of VC and ZrC, which are quite insoluble in one another were mixed with increasing amounts of TaC which has a metal atom size about halfway between the two and is capable of completely dissolving both. How much TaC would be required before a single homogeneous phase could be formed? Experiments to investigate this situation are in progress.

Conclusions

1. The monocarbides of the elements titanium, zirconium, vanadium, columbium and tantalum are isomorphous and have a sodium chloride type structure.

2. The binary carbide systems, TiC-ZrC, TiC-VC, TiC-CbC, TiC-TaC, ZrC-CbC, ZrC-TaC, VC-CbC, VC-TaC, CbC-TaC form continuous series of solid solutions.

3. The binary carbide system ZrC-VC shows very small solubility, the limits at 2100°C being 5 pct at the zirconium-rich end and less than 1 pct at the vanadium-rich end.

4. The parameter-composition curves show only slight deviations from Vegard's law but both positive and negative deviations are found.

5. The maximum size difference between atom diameters expressed in percent of the solvent atom diameter for extended solubility is 13 pct. The minimum value for very restricted solubility is 16 pct.

6. In the solid solution, the metal atoms are distributed at random on the points of the metal lattice.

Pressure Distribution in Compacting Metal Powders

POL DUWEZ* and LEO ZWELL*

Introduction

IN recent years, the problem of pressing metal powder in a die has received much attention. The question has been the object of a Symposium held in New York in March 1947 under the sponsorship of the AIME; an excellent review of the subject may be found in Ref. 1. Various experimental techniques have been used to study the behavior of the powder in a die cavity. Two methods have been particularly successful; one consists of measuring the density distribution^{2,3} and the other makes use of a lead grid in the powder during pressing.⁴ In the present study, the pressure at various points on the bottom and the sides of a die 1.50 in. in diam was measured by means of small piston dynamometers and resistance sensitive strain gauges. In order to correlate the results with previous investigations, the pressure distribution inside the compact has also been determined by an indirect method based on density measurements.

Strain Gauge Measurements of Pressure on Side and Bottom of Die

A schematic drawing of the die used for measuring side pressures is shown in Fig 1. The pressure gauge consists of a 0.25-in. diam piston A which transmits the pressure to a dynamometer B, on which two Baldwin Southwark type A-14 strain gauges are fastened 180° apart. Because the installation of several dynamometer assemblies along the side of the die would have been difficult, the pressure distribution was obtained in successive tests in which the distance from the gauge to the bottom of the compact was adjusted

FIG 1—Experimental die for measuring side pressure.

to different values by changing the length of the bottom piston. The dynamometer, disassembled from the die, was calibrated under compressive loads and showed a 1.00 ohm change of

resistance for every 15,300 psi change of pressure (750 lb load change).

All the strain gauge measurements were made with a null type Leeds and Northrup Wheatstone bridge. The sensitivity of the method was better than 1 pct and the accuracy was within 2 pct. These values were considered satisfactory in view of the rather large scatter in the measurements introduced by the random variation in packing the powder in the die. The stable ambient conditions and short time involved in the taking of observations made temperature compensation unnecessary.

The pressure distribution on the bot-

FIG 2—Pressure gauges on fixed piston.

tom of the die was determined with five dynamometers, as shown in Fig 2. The dynamometers were 0.25 in. in diam, 1.5 in. long, and had a 1 in. center length ground to 0.125 in. in diam. One Baldwin Southwark type C-7 strain gauge was pasted on each dynamometer. Under maximum loading, the elastic deformation of the dynamometers caused a relative displacement of about 0.0045 in. between the surface of the gauges and that of the bottom piston. In order to eliminate this source of error, an aluminum plug, 1.5 in. long, was placed under the piston with five steel inserts on which the dynamometers rested. Since the displacement of the aluminum plug with respect to the steel inserts compensated for the displacement of the dynamometers with respect to the bottom piston, the relative motion of the dynamometers to the bottom piston was negligible.

The average pressure acting on the fixed piston was measured by means of a strain gauge arrangement, shown in Fig 3. Four strain gauges, Baldwin Southwark type A-7, were attached around the dynamometer member of the piston. A calibration curve of gauge resistance with pressure was made by applying increasing loads with the moving piston acting directly on the fixed one.

PRESSURE ON THE SIDE OF A DIE

The copper powder used in the experiments was type MD-51 from

Metals Disintegrating Co., Elizabeth, N. J. The stainless steel powder was the 18-8 standard grade made by Unexcelled Chemical Co., New York City. The particle size distribution of the powders is given in Table 1.

Table 1 . . . Particle Size Distributions of Metal Powders

| Screen Size (mesh) Between and | | Weight of Particles in Each Size Fraction (per cent) | |
|--------------------------------------|-----|--|-------------------------|
| | | Copper | 18-8 Stainless Steel |
| 35 | 60 | 0.8 | |
| 60 | 100 | 88.2 | 1.2 |
| 100 | 150 | 5.8 | 5.2 |
| 150 | 200 | 1.2 | 7.0 |
| 200 | 325 | 1.0 | 24.4 |
| through | 325 | 3.0 | 62.0 |

The pressure on the side of the die was measured for both powders. For each location of the gauge with respect to the fixed piston, the applied pressure was increased in steps of 10,000 psi up to a pressure of 60,000 psi and in steps of 5000 psi up to a pressure of 100,000 psi. A family of curves of side pressure vs. applied pressure was then obtained, each curve corresponding to a point at a certain distance from the fixed piston. Typical curves (only two of each family) are shown in Fig 4 for copper and in Fig 5 for stainless steel. Each point on the curve represents the average of at least three measurements.

The results of pressure measurements are more conveniently analyzed by tracing curves of side pressure vs. distance of the gauge from the fixed piston for a given compacting pressure. Such pressure distribution curves are shown in Fig 6 for copper powder and in Fig 7 for stainless steel powder. Although the experimental points are rather scattered, they seem to fall more or less on straight lines. Hence, it may be concluded that the pressure on the side of the die increases almost linearly from the bottom to the top of the compact.

It is significant to note that the side pressure measured for copper powder is about twice as large as for stainless steel. It is probable that the most important factor influencing the side pressure in a die is the plasticity of the powder. A soft powder is likely to flow sidewise and produce a higher lateral pressure than a hard powder. In order to substantiate this statement, side pressure measurements were made by replacing the powder with a cylinder of solid copper. With a fully annealed cylinder (Rockwell F30) the side

pressure was about 50 pct greater than that measured with the powder. With a hard copper cylinder (Rockwell B47) the side pressure was 50 pct less than that observed with the powder. These results suggest that a systematic investigation of the effect of hardness of the powder on the side pressure would be very worthwhile.

PRESSURE DISTRIBUTION ON THE FIXED PISTON

A series of measurements was made with the five small gauges previously described in an attempt to determine the variation in pressure along two perpendicular diameters of the fixed piston. Numerous measurements were made with different thicknesses* of compact and at various compacting pressures. Only a typical set of curves is shown in Fig 8 for compacts of various thicknesses and a compacting pressure of 50,000 psi. The abscissa of the graph of Fig 8 is the distance from the center of the fixed piston expressed as a fraction of the radius of the piston. The results indicate clearly that the

* The word "thickness" refers to the dimension measured after the compact was ejected from the die.

FIG 3—Fixed piston gauge for measuring average pressure.

FIG 4—Variation of side pressure with compacting pressure for copper powder, compact thickness 1.15 in., compact diameter 1.51 in.
 (○) 1.0 in. from fixed piston.
 (●) 0.15 in. from fixed piston.

pressure on the fixed piston decreases steadily from the center to the periphery of the piston. Moreover, as the thickness of the compact increases, the average pressure on the fixed piston decreases, but the shape of the pressure distribution curve does not change appreciably, at least within the limits of thickness to diameter ratios considered in these measurements. It is also interesting to note that for a thin compact (ratio of thickness to diameter equal to 0.11 on Fig 8), the pressure at the center of the fixed piston is greater than the compacting pressure.

The results of this series of experiments were substantiated by the measurements of the density distribution within a compact (See "Pressure Distribution within a Compact").

AVERAGE PRESSURE ON THE FIXED PISTON

In spite of the fact that the pressure is not uniform on the fixed piston, the consideration of an average pressure is of interest because it introduces simplifications in both experimental technique and interpretation of the results. Experiments were therefore made with the purpose of relating the average pressure on the fixed piston with the thickness of the compact. The results of measurements are presented in Fig 9. In this diagram, the two variables are dimensionless, the ordinate being the ratio of base pressure to applied pressure and the abscissa the ratio of thickness of compact to diameter. These results were obtained with copper powder at compacting pressures of 40,000 and 100,000 psi. The scatter of the results is relatively large and may

be attributed to the difficulty in obtaining a uniform packing of the powder during loading. In spite of the scatter, it seems reasonable to conclude that, in a first approximation at least, the ratio of bottom pressure to compacting pressure is a function of the ratio of thickness to diameter of compact and in the range of pressures from 40,000 to 100,000 psi does not depend upon the compacting pressure.

The variation of fixed piston pressure with the thickness of a compact is of great practical interest, since it shows what fraction of the compacting pressure is actually transmitted to the bottom of the compact. It is significant to note the rather rapid decrease in bottom pressure with increasing thickness of compact. For the copper powder

used in the present experiments, and with a ratio of thickness to diameter equal to 1.0, only about 30 pct of the compacting pressure is acting on the bottom part of the compact.

The rather simple technique of measuring the average pressure on the fixed piston seems to be best suited to characterize the behavior of a powder during compacting. Its use should prove of great interest for studying quantitatively the effect of lubricants added to the powder or sprayed on the die walls.

Several investigators have proposed theoretical explanations for the decrease in fixed piston pressure with increasing compact thickness. The parabolic expression given by Unckel⁵ does not give a satisfactory agreement with the results found in the present investigation. The exponential relation derived by Taylor⁶ agrees with the results only for compacts having a thickness to diameter ratio less than one.

Pressure Distribution within a Compact

The pressure distribution within a compact was determined by an indirect method, based on the relation between the local density within the compact and the compacting pressure that would be required to obtain such a density. A calibration curve of density vs. compacting pressure was first obtained by pressing $\frac{1}{8}$ -in. thick compacts at various pressures and measuring their densities. In spite of the relatively small ratio of thickness to

FIG 5—Variation of side pressure with compacting pressure for stainless steel powder, compact thickness 1.27 in., compact diameter 1.51 in.
 (○) 1.0 in. from fixed piston.
 (●) 0.15 in. from fixed piston.

FIG 6—Pressure distribution on the side of a die for copper powder under various compacting pressures; compact thickness 1.15 in.

FIG 7—Pressure distribution on the side of a die for stainless steel powder under various compacting pressures; compact thickness 1.27 in.

diameter of these compacts (0.083), the strain gauge pressure measurements showed a base pressure about 6 pct smaller than the compacting pressure. An average pressure was then taken for tracing the calibration curve. Such a curve is shown in Fig 10 for copper powder. The densities of successive layers in a thick compact were obtained by facing off cross-sections of the compact and computing their densities from the dimensions and weights of the compacts before and after machining. In order to eliminate errors due to machining, some compacts were faced from top to bottom, others from bottom to top, and still others from both ends to the center.

The radial distribution of density was determined by turning down the diameter of compacts in steps of 0.20, 0.25, 0.35, and 0.70 in. for thicknesses varying from $\frac{1}{4}$ to $\frac{1}{2}$ in. and computing the densities of these machined cylindrical sections. The densities of the compacts and sections were computed with an uncertainty of about 1 pct and the uncertainty in the pressure values was estimated to be about 6 pct.

The pressure distribution in the vertical direction is shown in Fig 11 for a series of compacts pressed at 100,000 psi. The different symbols used on this

graph refer to specimens having various thicknesses after compacting. The ordinate of the diagram is the ratio of the average effective pressure in a given section of the compact to the applied compacting pressure. The abscissa is also a ratio, obtained by dividing the distance between a section of the compact and the moving piston by the diameter of the compact. This method of presenting the data has the advantage of dealing with dimensionless parameters. The rather large scatter in experimental results (See Fig 11) is probably due mostly to the nonuniform distribution of the powder in the die before pressing. In spite of the scatter, the results indicate that the pressure distribution is about the same for all compacts, regardless of thickness.

As expected, the average pressure decreases steadily from the top to the bottom of the compact. It is interesting to note, however, that for a ratio of thickness of compact to diameter greater than approximately 1.0, the pressure tends to decrease slowly, and approaches a value equal to about 20 pct of the applied pressure on the moving piston.

FIG 11—Pressure distribution in copper compacts of various thicknesses, compacting pressure 100,000 psi.
(○) 0.65 in., (△) 1.2 in., (▽) 1.5 in., (×) 2.4 in.

A comparison of the results in Fig 9 and 11 shows that there is satisfactory agreement between the values of the pressures on the fixed piston measured by strain gauges and the values of the pressures at equivalent depths of compacts determined from density measurements. The small difference observed in the two figures (the fixed piston measurements being slightly higher) may be due to the different radial pressure distributions in the two cases and to the different character of the contact layer; that is, at the fixed piston the powder is pressed against a solid support, while within the compact

the powder is pressed against a soft support.

Additional results were obtained at pressures of 80,000 and 40,000 psi. In this case, it was possible to use longer compacts, for which the ratio of thickness to diameter was about 3.4. The results presented in Fig 12 indicate that the pressure distribution curves are reasonably close to the average curve obtained for 100,000 psi. The tendency for the pressure to level off in the bottom portion of long compacts, already mentioned in connection with the measurements made at 100,000 psi, is still more apparent from the graph of

Fig 12. It seems reasonable to conclude that in the range of pressures of 40,000 to 100,000 psi, the pressure distributions in the die are similar. This result cannot be extrapolated to lower pressures. It was found, for example, that for a compacting pressure of 15,000 psi (See Fig 13), the pressure distribution curve does not fall as rapidly as for higher compacting pressures. This observation agrees with a generally recognized fact, that at low compacting pressures the uniformity of pressure (or density) in the longitudinal direction of a cylindrical compact, is relatively better than at high compacting pressures.

The pressure distribution in the radial direction and at various depths within a compact was also investigated by the density method. The results are rather complex, because the three dimensional pattern of pressure distribution depends on the thickness of the compact, and changes continuously as the compacting pressure increases. The results obtained with three compacts of different thicknesses and a compacting pressure of 100,000 psi are presented in Fig 14, 15, and 16. For all three specimens, the effective pressure near the moving piston is much higher at the outer circumference of the compact than at the center. This non-uniformity in pressure distribution decreases with the thickness of the compact and disappears at some distance from the top. In approaching the fixed piston, the situation is reversed, and the pressure decreases from center to periphery. This last observation is in agreement with the pressure measurements made with the five gauges on the fixed piston previously described. By comparing the graphs of Fig 14, 15, and 16, it is evident that the uniformity of pressure on the fixed piston is better for thicker compacts. This uniformity is obtained at the expense of the average pressure, which is, of course, very low on the bottom of a thick compact.

Additional measurements made with a compacting pressure of 50,000 psi did not alter essentially the shape of the pressure distribution curves obtained for 100,000 psi. It is probable that for low pressures of the order of 10,000 or 20,000 psi the distribution of pressure is more uniform. At low pressures, however, density measurements were difficult because of the lack of strength of the compacts.

An attempt was made to represent the distribution of pressure within a compact by tracing lines of equal pres-

sure in a longitudinal section. Three cases corresponding to compacts having a thickness to diameter ratio of 0.42, 0.79, and 1.66 are shown in Fig 17. Although these tracings should not be considered as very accurate, they provide a useful illustration of the results previously discussed.

The results of the present investigation of radial and longitudinal distributions of pressure agree in general with those obtained by Kamm, Steinberg and Wulff with the use of a lead grid in the powder during pressing.⁴

Summary and Conclusions

The experiments described in this paper have established the possibility of using resistance type strain gauges for measuring the pressure distribution on the walls and on the fixed piston of a die. The pressure on the walls in a cylindrical die varies almost linearly from the bottom to the top of the compact. On the fixed piston, the pressure decreases from the center to the periphery. The average pressure acting on the fixed piston or the die was also measured by a very simple strain gauge technique.

An interesting curve characterizing the behavior of the powder was obtained by plotting the ratio of the pressure on the fixed piston to the compacting pressure vs. the ratio of thickness to diameter of the compact.

The distance from the moving piston appears to be the basic factor determin-

ing the magnitude of effective pressure at any section of a compact; that is, variation of base pressure measurement with thickness of compact (distance from moving piston) agrees reasonably well with the variation of effective compacting pressure with depth of compact (distance from moving piston).

There is a radial distribution of pressure at the top and bottom of the compacts. Near the moving piston, the pressure is high at the outer edge and decreases towards the center. At the fixed piston, the pressure is higher at the center of the compact and decreases towards the outer edge. While the radial distribution at the top is always present, the radial distribution at the base of the compact decreases with increasing thickness of compact until it vanishes, in the case of copper, at a thickness to diameter ratio of about 1.5.

Preferred Orientation in Rolled and Recrystallized Beryllium

A. SMIGELSKAS* and C. S. BARRETT,† Member AIME

THERE have been no publications of the deformation and recrystallization orientations of the metal beryllium, yet pronounced textures would certainly be anticipated since it is close-packed hexagonal in structure. Having an axial ratio approximately that of magnesium, beryllium probably deforms by nearly the same slip and twinning mechanisms that operate in magnesium, and the textures are likely to be similar or but slightly different from the magnesium textures. In the tests reported below this is found to be the case; the textures are found to differ from those of magnesium only in the details of the scatter from the average orientation.

This report covers not only samples rolled at room temperature, but some rolled at elevated temperatures. Since magnesium has been suspected by some investigators of altering its crystallographic deformation mechanism at elevated temperatures, it was considered possible that beryllium might do so and alter its textures accordingly. No pronounced alterations were found, however. Unfortunately, the theory of deformation textures is not in a state of development that permits one to deduce the deformation mechanism from a knowledge of the textures, which means that the similarity of textures at different rolling temperatures, reported here, cannot be taken as definite evidence that the deformation mechanism is actually the same at all temperatures. The general similarity of the deformation textures of magnesium and beryllium also extend to the recrystallization textures of the two metals, judging by the pole figures for recrystallized sheet presented in this report.

Methods

Samples were prepared in the form of composite sheets made up of small pieces stacked in a pile. Each piece was trimmed with scissors so that an edge was parallel to the rolling direction, dipped in paraffin, and assembled into the pack by aligning it under the cross hair of a microscope. As the desired orientation was obtained on each piece it was secured in place by touching with a hot wire to melt the paraffin. A stack of ten or fifteen pieces was built up in this way, then trimmed to the shape of a T; the portion to be X rayed was then etched to the shape of a wire about 0.045 in. diam with 6N HCl. This method of shaping the sample is a modification of that used by Bakarian on magnesium.¹ The absorption of the rays in the sample was so slight that it caused no difficulty in interpreting the films.

Exposures were made with a 0.030 in. diam pinhole, using molybdenum radiation (40 kv, 25 ma, Type A film at 5 cm, 2 to 3 hr exposures). With the recrystallized specimens it was found necessary to oscillate the specimen so as to reduce the spottiness of the lines. A range of oscillation of 5° was suffi-

cient to produce reasonably satisfactory patterns, though the quality was somewhat inferior to that of the deformation texture patterns, and only two degrees of intensity were read from the arcs on the films. Typical photographs for each of the deformation textures and the recrystallization texture are assembled in Fig 1.

The pole figures were plotted in the usual way with the intensity of the various portions of the diffraction rings estimated by eye. Seven to nine films were made of each sample and each was carefully read in plotting the pole figures.

Typical series included exposures with the beam normal to the rolling direction and at 11, 26, 41, 56 and 71° to the cross direction, plus two exposures with the beam normal to the cross direction, and at 11 and 79° respectively to the rolling direction.

The rolling was in each case considered sufficient to develop the final texture: the reduction by cold rolling was 84 pct (from 0.0045 to 0.0007 in. thickness), following prior hot rolling in longitudinal and transverse directions and recrystallization; the reduction by hot rolling at 800°C was 90 pct (0.010 to 0.001 in.), following similar prior treatment; the reduction by rolling at 350°C was 88 pct (from 0.005 to 0.0006 in.) after similar prior treatment. The recrystallization texture was determined on a sample rolled at 350° to a reduction of 88 pct (0.0165 to 0.002 in.) after similar prior treatment, then mounted between steel strips to keep it flat and annealed at 700° in an atmosphere of argon.

Discussion of Results

The results of the X ray determinations are assembled in the pole figures of Fig 2, 3, 4 and 5 for rolling at

FIG 1—X ray photographs (a) room temperature rolled sheet (b) 350°C rolled sheet (c) 800°C rolled sheet (d) 350°C rolled sheet and recrystallized at 700°C.

Beam 11° to cross direction and 90° to rolling direction vertical. Outmost ring (101) pyramidal planes show eight maxima; next ring (001) basal plane shows two maxima in 3 o'clock and 9 o'clock positions; the inner ring (100) planes show maxima at 6 o'clock and 12 o'clock positions.

25, 350 and 800°C and for 350°C rolled sheet after recrystallization, respectively. The plane of the sheet is parallel to the plane of the stereographic projection in all the figures, with the rolling direction vertical and the transverse direction horizontal. The densities of the arcs on the films are indicated by the closeness of the cross-hatching on the pole figures. The orientations of three different sets of planes are shown, the three with most marked evidence of orientation in the films, (0001), (10 $\bar{1}$ 0), and (10 $\bar{1}$ 1), that is, (001), (100), (101). The conclusions that are drawn from these data are consistent with the pole figures from all three sets of planes.

The texture is of the same type in all specimens. It may be described in terms of an ideal, or mean, orientation plus a scatter, the ideal orientation being (001) parallel to the plane of rolling and (100) perpendicular to the direction of rolling. This orientation is

shown on each of the pole figures by small circles. Thus the basal plane is parallel to the plane of the sheet; two close-packed rows of atoms in this plane make an angle of 30° with the rolling direction, and the third close packed row is parallel to the transverse direction in the sheet.

The scatter from this mean position is such that the hexagonal axis tilts more toward the cross direction than toward the rolling direction. To state it differently, treating the rolling direction as an axis of rotation, the scatter around this axis extends as much as 50° each way from the mean orientation, while the scatter around the cross direction is only about 20° each way from the mean.

From the pole figures it appears that the scatter is greatest with room temperature rolling, is less with 350°C rolling, and still less with 800°C rolling and with recrystallization, the corresponding ranges of scatter around the

rolling direction as an axis being about 65, 50, 40, and 40° from the mean orientation, respectively. Whether these different ranges are significant is problematical, however, for it must be noted that the grain size progressively increases throughout this sequence, hence the films are progressively less able to locate with certainty the exact limits of a pole figure area.

There is no evidence of an abrupt change in texture at an elevated temperature that would necessitate assuming that a different mechanism of deformation sets in above room temperature. But as mentioned earlier, it is not possible at the present time to definitely exclude this on the basis of the pole figure evidence, since a complete understanding of textures and their implications has not yet been reached.

The mean position of the basal plane in rolled beryllium (axial ratio $c/a = 1.568$) is the same as in magnesium, zirconium, and close-packed hexagonal

cobalt, ($c/a = 1.624, 1.589$ and 1.624 respectively), but differs from that in zinc and cadmium, which have much greater axial ratios (1.85 and 1.88 respectively). Twinning is an important feature of the rolling process for zinc and cadmium and not for the metals of lower c/a ratio, and we now see that beryllium is no exception to this rule, for there is nothing in the texture of beryllium that suggests an appreciable amount of twinning in the final stages of deformation. There may be twinning, of course, in the early stages of deformation before the stable texture is reached.

It is not surprising that the recrystallization texture is the same as the rolling texture, for this is a common behavior in close-packed hexagonal metals.

There is no evidence for the double texture that is observed in certain alloys of magnesium,¹ in which the central spot of the (001) pole figure is

double. The major axis of spread in beryllium is around the rolling direction of the sheet, which is similar to zirconium, rather than around the transverse direction as in magnesium.² Another interesting feature of the beryllium texture is the alignment of the [210] direction parallel to the rolling direction (that is, the alignment of the (100) plane normal to the rolling direction). In the usual textures reported for hexagonal metals there is no marked preference for any direction in the basal plane to be parallel to the rolling direction.

Summary

The rolling texture of beryllium is one in which the preferred position of the basal plane is parallel to the plane of the rolled sheet and close-packed rows of atoms in this plane lie 30° from the rolling direction. There is a scatter of from 40 to 65° in both directions

from this orientation around the rolling direction as an axis, and a smaller scatter around the transverse direction in the sheet. The texture is approximately the same for rolling at room temperature, 350 and 800°C , and after recrystallization. There is no evidence of a change of slip mechanism with temperature.

Acknowledgments

We are indebted to Mr. James F. Schumar and Mr. S. Hugh Paine, Jr., for assistance in this work, and particularly to Mr. Robert E. Macherey for the difficult rolling of the samples. The work described in this article was performed under the auspices of the Atomic Energy Project.

Magnesium-lithium Base Alloys— Preparation, Fabrication, and General Characteristics

J. H. JACKSON,* P. D. FROST,* A. C. LOONAM,* L. W. EASTWOOD,* and C. H. LORIG,* Members AIME

Introduction

It is well known that for equal weights of material, thin sections of the lighter structural alloys are more resistant to buckling under a compressive stress than thin sections of more dense material. Therefore, structural parts having the same resistance to buckling stresses are generally lightest when they are made of magnesium alloys. Consequently, there is considerable interest in the development of strong alloys having densities equal to or lower than that of magnesium and strength-weight ratios equivalent to those of the strongest aluminum alloys.

The development of commercial magnesium-base alloys has been very successful, and their importance among materials in the structural field has been amply demonstrated. However, an even wider structural application of magnesium alloys might be effected if improvements could be made in the cold rollability and cold-forming characteristics. Such improvements, along with production of less directionality in properties, could be effected if the hexagonal close-packed lattice of present alloys could be replaced with a cubic lattice.

In 1942, a project, having as its objective the improvement of some of the characteristics of commercial magnesium-base alloys, was initiated at Battelle Memorial Institute under the sponsorship of the Mathieson Chemical Corporation. At that time, one of the authors,* then Chief Metallurgist for the Mathieson Chemical Corporation, postulated that the addition of lithium to magnesium in sufficient quantities to change the crystal structure of the resultant alloy from a hexagonal to a

body-centered cubic lattice should produce a magnesium-rich alloy which would have the desired improvements in cold-working characteristics with less directionality in properties. To test this view, a series of alloys was made and was found to have many of the attributes that were predicted.

The view that magnesium-lithium alloys were of structural interest was also held by others. In 1943 and 1945, Dean and Anderson^{1,2} obtained patents on magnesium-base alloys containing from about 1 to 10 pct lithium, from about 2 to about 10 pct manganese, and the balance substantially all magnesium; and on magnesium-base alloys containing from about 1 pct to about 10 pct lithium, from about 2 to about 10 pct manganese, from about 0.5 to 2 pct silver, and the balance substantially all magnesium. They noted that an alloy containing 83 pct magnesium, 10 pct manganese, 5 pct lithium, and 2 pct silver could be cold rolled by any of the usual methods and that this alloy was considerably harder and stronger than most other magnesium-base alloys heretofore available.

In 1945, Hume-Rothery, et al.,³ predicted that magnesium-lithium base alloys should be soft and ductile and that such compositions, to which was added a third element for the purpose of producing a precipitation-hardening type of alloy, should be ductile, strong, and lighter than magnesium itself. Hume-Rothery investigated the

binary magnesium-lithium and ternary magnesium-lithium-silver equilibrium relations and criticized the existing equilibrium diagrams. The binary magnesium-lithium equilibrium diagram has also been investigated by Grube, Von Zeppelin, and Bumm,⁴ Henry and Cordiano,⁵ Sal'dau and Shamrai,⁶ Hofmann,⁷ and Shamrai.⁸ The work of most investigators agreed with that of Grube, whose constitution diagram is shown in Fig 1.

From the standpoint of development of structural alloys, the room-temperature equilibrium relations are of great interest. An examination of Fig 1 reveals that, from 0 to 5.7 pct lithium, the existing phase is alpha, which is a solution of lithium in hexagonal magnesium. The boundary between the alpha, and alpha plus beta regions, occurs at a Mg/Li of 16.5, corresponding to 5.7 pct lithium by weight. Between 5.7 pct and 10.3 pct lithium, there exists a mixture of the alpha phase (lithium dissolved in hexagonal magnesium) and the beta phase (magnesium dissolved in body-centered-cubic lithium). The boundary of the alpha plus beta and beta regions occurs at a Mg/Li of 8.7, corresponding to a lithium composition of 10.3 pct. Much of the work described here was directed toward obtaining an alloy made up of a large proportion, or entirely, of the body-centered-cubic beta structure.

In his early work, Loonam found that specimens of lithium-bearing alloys were very malleable. Ingots of alloys prepared at that time were extruded to $\frac{3}{8}$ -in. diam bars, and the mechanical properties and the effects of heat treatment were then determined. These data are given in Table 1. The outstanding ductility of the alloys, combined with their moderately high strength, evoked considerable interest.

¹ Alloys were prepared at Mathieson and tested at Battelle.

² Extruded to 3/8-in.-diam rod. Reduction of 10 to 1.

³ Protected from oxidation with argon atmosphere.

The fact that aluminum-bearing alloys, Nos. 5, 6, and 7, were hardened by water quenching from 950°F indicated that, by suitable heat treatment, higher strengths could be obtained. In order to explore completely the possibilities of magnesium-lithium alloys, an extensive project at Battelle was set up by the Mathieson Chemical Corporation. In 1945, when magnesium-lithium base alloys were found to be of military interest, the Navy Department, Bureau of Aeronautics, entered into a cooperative agreement with Mathieson for the sponsorship of further investigational work.

This paper summarizes the results obtained during the several years of investigation of the magnesium-lithium base alloys. These results are described under seven main topics covering melting technique, fabricating practice, density measurements, mechanical properties, work-hardening and stability characteristics, corrosion resistance, and metallographic structure.

Melting Techniques

Magnesium-lithium base alloys can be melted satisfactorily under a flux or under an inert atmosphere. The flux, when it is used, is comprised of lithium chloride and lithium fluoride in the proportions from 75/25 to 82/18, the choice of the composition depending to a great extent upon the alloy composition to be melted. In general, better separation of the metal from the flux is obtained when the salts are in the ratio of 75 to 25; hence, a flux of this composition is selected when a new type of alloy is melted for the first time. However, when this flux is used on certain alloys, especially those containing high percentages of cadmium, it tends to become very viscous. A change to the 82/18 composition will, in most instances, improve the fluidity, although the flux of higher lithium chloride content does not separate from the metal as well as does the flux of lower lithium chloride content.

In most of the experimental work, the quantity of flux used was equivalent to about 35 pct of the weight of the metallic charge. When "large" heats were made, that is, heats weighing 10 lb or more, it was possible to reduce the percentage of flux. The flux can be re-used, and if it becomes too thick for easy handling, the addition of unused material will increase its fluidity. To make certain, however, that the flux would be satisfactory on heats prepared for the experimental studies, fresh materials were used for each melt.

A crucible having a diameter about one-third its height is used in preparing the melts. The flux is melted first to eliminate all traces of water from the hygroscopic flux ingredients. The magnesium and alloying elements other than lithium are then added. In order to insure that the alloying elements dissolve, they are placed in a steel wire basket suspended in the molten magnesium. Before the lithium is added,

FIG 3—Melting crucible, showing relative positions of flux and metal after lithium addition.

the molten flux is lighter than the metal and provides an effective protective layer on the melt, as illustrated in Fig 2. Lithium, added by means of an inverted cup, is plunged below the surface of the metal bath. After the lithium dissolves, the cup is removed and the melt is thoroughly stirred.

The addition of lithium to the magnesium reduces the density of the alloy to a value lower than that of the flux, and the metal then floats on top of the flux, as shown in Fig 3. If the desired alloy contains elements which can be introduced into the metal more easily by the reduction of the salt of the element, such salt additions are made at this time. This addition can readily be introduced by melting the correct proportion of salt in a separate pot containing lithium chloride-lithium fluoride flux and then pouring the molten salt and flux mixture onto the metal bath. Should the element added in the form of salt not be soluble in molten magnesium alone but soluble in the magnesium-lithium melt, then the above procedure has various obvious advantages.

After all alloying additions are made, the flux is allowed to settle in the crucible. It is often desirable to make additions to the flux in order to increase its density and thus decrease the settling time. An addition of about 10 pct lithium bromide is especially effective.

It is desirable to equip the crucible with a sump in the bottom into which the flux may collect. A convenient method to avoid the mixing of metal and flux during pouring involves the insertion of a cover so that the cover rests on the sump and holds the flux in

the sump while the metal is poured.

Although the flux is heavier than the metal after the lithium addition, a thin film of flux remains on the surface. The protection offered by this film, combined with the stack effect of the deep crucible, reduces the tendency toward burning or excessive oxidation of the metal. Magnesium-lithium base alloys are protected during pouring by a thin film of oxide which envelops the stream. The Durville method of pouring, or a slight modification of it, is necessary if turbulence and attendant inclusion of the oxide skin in the ingot are to be avoided. Therefore, the molds are tilted in such a way that the metal runs down the side with a minimum of turbulence. Ingot molds of either graphite or cast iron are satisfactory. When a cast iron ingot mold is used, a hot top either of graphite or of a refractory baked at high temperature is needed. The surfaces of cast iron molds are coated with acetylene soot. Before pouring, both graphite and cast iron molds are heated to about 250°F to drive off moisture. After pouring, any tendency toward burning on the surface of the ingot hot top is eliminated by the use of G-1 powder (a commercial graphite-base material) or paraffin, or by covering with an air-tight lid. By following the procedure described, the magnesium-lithium base alloys are less likely to burn during melting and pouring than are ordinary magnesium-base alloys.

Magnesium-lithium base alloys may be melted under argon in a capped crucible without the employment of a salt flux. To take full advantage of the inert atmosphere, it is desirable to

place the entire charge, including the lithium, into a cold crucible. After purging the crucible with argon, the heat is melted and poured. Only a slight tendency toward burning during the pour is evident even though no salt flux is used.

A melting procedure combining the use of a flux and an argon atmosphere is also highly satisfactory, and by this technique the amount of flux required can be drastically reduced. The use of an argon atmosphere reduces oxidation and lessens the tendency for the flux to thicken.

Fabrication Practice

For the most part, the magnesium-lithium base alloys were cast into one or more of the various ingots described in Table 2. The ingots were fabricated to produce test material also described in Table 2.

The recrystallization temperature of many magnesium-lithium base alloys of the body-centered-cubic lattice type is about 375°F. The alloys can be hot worked readily by extruding, hammer forging, or hot rolling at temperatures between 400 and 700°F, depending on composition. Finishing temperatures at or just above the recrystallization temperature of 375 to 425°F were used in the experimental work in order to obtain a fine-grained product.

The reduction by hot rolling depended to some extent upon the alloy composition and, in general, was about 30 pct per pass. Hot rolling could be accomplished, however, at reductions as high as 50 pct per pass on most alloys. In order to prevent the magnesium-lithium alloy from adhering to the rolls, the latter were usually coated with kerosene for both hot and cold rolling.

The rolls during cold rolling were usually kept near room temperature. Practically all compositions could be cold rolled to total reductions of at least 15 pct immediately after hot rolling or after solution treating; in some instances, they could be cold rolled to total reductions of over 95 pct. Many of the alloys could be cold reduced as much as 50 to 75 pct per pass, although the general practice was to restrict cold-rolling reductions to 5 to 10 pct per pass.

The magnesium-lithium base alloys could be cold drawn to bar stock only with difficulty because of their tendency to seize on the die and because they

FIG 4—Effect of lithium on ductility and yield strength of extruded magnesium.

work harden only to a limited extent. The latter makes it difficult to strengthen the tip to resist fracture as the bar is started through the die. Various lubricants for cold-drawing operations were tried in an attempt to prevent die seizure. The only lubricating practice that has been successful involved the use of a flash coat of copper applied by dipping the magnesium-lithium bar in a solution of copper sulphate made slightly alkaline by the addition of ammonium hydroxide.

Density of Magnesium-lithium Alloys

One characteristic of great interest is the low density of the magnesium-lithium base alloys. A binary alloy containing 11.5 pct lithium has a density of approximately 1.4 g per cc; however, this binary alloy is so soft and ductile that it has little value from the structural standpoint, except where low strength is permissible and good formability is desired. If sufficient alloying additions of the heavier metals are made to this alloy to improve its strength, the density is often increased to about 1.45 to 1.65 g per cc. It is not difficult to formulate a magnesium-lithium alloy having mechanical properties superior to the commercial magnesium-base alloys and having a density considerably less than 1.8 g per cc, which is approximately the density of most commercial magnesium alloys.

FIG 5—Effect of lithium on bend ductility of magnesium.

Some Mechanical Properties of the Magnesium-lithium Alloys

MAGNESIUM-LITHIUM BINARY ALLOYS

Magnesium-lithium binary alloys have hardnesses of the order of 0 to 10 on the Rockwell E scale, which is equivalent to a Brinell hardness number of about 30 to 35. Magnesium-lithium base alloys having good mechanical properties have hardnesses of the order of 90 Rockwell E, which is equivalent to a Brinell hardness number of about 85.

One of the most important properties which lithium was found to bestow upon magnesium was increased ductility. Although the body-centered-cubic lattice structure does not exist below 5.3 pct lithium, as little as 2 pct lithium markedly enhanced the tensile ductility and formability of pure magnesium. The effect of lithium on tensile ductility is shown in Fig 4. It will be noted that a pronounced increase in reduction of area, accompanied by a marked decrease in yield strength, occurred as lithium was increased from 8 to 13 pct. This is explained by the transition, at 10.3 pct lithium, from the two-phase, hexagonal plus body-centered-cubic structure, to the single-phase, body-centered-cubic structure. Although the single-phase hexagonal and the two-phase alloys were by no means neglected in the experimental work, the greatest attention was paid to alloys with a body-centered-cubic structure.

The influence of lithium on the bend ductility of pure magnesium is shown in Fig 5. The increase in bend ductility of rolled alloys in going from the two-phase region to the region of 100 pct beta was very noticeable. For example, the 9 pct lithium, alpha- plus beta-

phase alloy could not be bent more than 90° while the 11 pct lithium, beta-phase alloy withstood a 180° bend. On the other hand, in the extruded condition, the 9 pct lithium, two-phase alloy, had bend ductility which was equal to that of the 11 pct lithium, beta-phase alloy. The superior bend ductility of the alpha- plus beta-phase alloy in the extruded state can be explained by the mode of occurrence of the alpha phase in the microstructure. The microstructure of the alloy in the extruded and hot-rolled states is shown in Fig 6. The alpha phase occurs in the form of more or less randomly oriented, short patches in the extruded material, whereas in the rolled material it occurs as long platelets, with the plane of the platelets parallel to the plane of the sheet. When the materials are bent, the long, brittle alpha platelets in the sheet are more prone to break and notch the beta material than are the short, brittle alpha patches in the extruded material.

The effect of lithium on the cold rollability of magnesium can be observed from data plotted in Fig 5. Whereas commercially pure magnesium failed in rolling after a cold reduction of 19 pct, the lithium-bearing alloys could be cold-rolled at least 45 pct. In the cold-rolled state, the lithium-bearing alloys retained nearly the same bend ductility they possessed in the hot-rolled state.

MAGNESIUM-LITHIUM-BASE TERNARY ALLOYS

Among the original alloys prepared at the Mathieson Chemical Corporation were several which contained aluminum or zinc. The mechanical properties of the alloys with aluminum or zinc gave ample indication that these elements would be of importance in increasing the strength of the ductile magnesium-lithium base. In later work, effects of practically all of the metallic elements on the properties of the magnesium-lithium alloys were investigated by preparing and studying over 1800 individual heats.

The order of solid solubility of the elements in the beta phase at room or slightly elevated temperatures, as determined from the many experimental investigations, is roughly as follows:

| Most Soluble Elements | | |
|-----------------------|----|----|
| Ag | Cd | Al |
| | Hg | In |
| | Zn | Tl |

Slightly Soluble Elements

| | | | | |
|----|----|----|----|----|
| Ni | Cu | Ca | Si | Sb |
| Co | | Sr | Ge | Bi |
| | | Ba | Sn | |
| | | Ce | Pb | |

Relatively Insoluble Elements

| | | | | | |
|---|----|----|----|----|----|
| | Be | Cr | Ti | V | Mn |
| K | B | Mo | Zr | Cb | |
| | | W | Th | | |
| | | U | Fe | | |

The elements which most effectively increased the mechanical strength of the magnesium-lithium base were aluminum, zinc, silver, and cadmium. An example of their effectiveness is shown in Fig 7. In this figure are plotted the maximum and minimum yield strengths obtained from a series of about 50 different ternary alloys of 8.1 Mg/Li base. At the extreme left, the yield strength of the 100 pct beta, 8.1 Mg/Li binary alloy is shown to be 12,000 psi. Antimony added in amounts of 1 to 4 pct and bismuth in amounts of 2 to 4 pct did not increase the yield strength. However, the recovery of

these two elements in magnesium-lithium base alloys has consistently been very low. Copper increased the yield strength somewhat, but 1 pct copper was, for all practical purposes, equally as effective as 8 pct.

Substantial increases in yield strength were brought about by additions of silver, zinc, cadmium, and aluminum. In this series of alloys, 0.5 pct aluminum was as effective as 4 pct zinc, and was much more effective than either 2 pct cadmium or 4 pct silver. The elements which were most effective in alloys with a magnesium-lithium ratio of 8.1 were likewise very effective at other magnesium-lithium ratios.

Some interesting effects of aluminum and zinc on the properties of ternary alloys having various magnesium-lithium ratios are shown in Fig 8 and 9. The alloys with a magnesium-lithium ratio of 24 (24 Mg/Li) are of the hexagonal alpha phase, those with magnesium-lithium ratios of 13.3 and 9.7 consist of alpha plus beta, and those with a magnesium-lithium ratio of 8.1 consist of the body-centered-cubic

FIG 7—Effect of various elements on the yield strength of the 8.1 Mg/Li beta solid solution. All alloys tested in the as-extruded condition.

FIG 8—Effect of aluminum at different magnesium-lithium ratios on mechanical properties of extruded ternary alloys.

beta phase. The results plotted in these figures show that (1) several alloys possess rather good properties, a fact which offered an incentive for further investigation; (2) the elongation tends to increase as Mg/Li decreases; and (3) as Mg/Li decreases, there is an increase in the ratio of yield strength to tensile strength. In general, the yield strengths of the high-strength, magnesium-lithium alloys are proportionally high and are the same in tension and compression.

MAGNESIUM-LITHIUM BASE QUATERNARY AND QUINARY LOW-LITHIUM ALLOYS

The favorable properties observed for some of the ternary alloys proved an incentive to investigate quaternary and quinary alloys. The tensile properties of a 24 Mg/Li series of alloys having the hexagonal structure are shown in Fig 10. The average tensile strength of this series of alloys was about 45,000 psi.

MAGNESIUM-LITHIUM BASE QUATERNARY AND QUINARY HIGH-LITHIUM ALLOYS

The above data suggested the possibility of developing interesting alloys having the hexagonal structure or the two-phase, hexagonal plus body-cen-

tered-cubic structure. Of even greater interest have been the beta-phase, cubic lattice alloys, that is, alloys having magnesium-lithium ratios under 8.7. Alloys with magnesium-lithium ratios of 8.1, 7, 6, and 5 have been investigated in detail. A minor amount of work has also been done on 3.5 Mg/Li alloys.

In one series of 12 heats, the effects of variations in aluminum, cadmium, and silver in quinary alloys having a magnesium-lithium ratio of 6, with aluminum varying from 2 to 12 pct, silver varying from 0 to 4 pct, and cadmium varying from 0 to 4 pct were determined. The compositional levels were selected and the experiment performed as a factorial design. By means of this experimental technique, the individual effect of each of the three alloying additions, cadmium, silver, and aluminum, could be determined independent of the effects of the other two additions. The mechanical properties of the alloys are shown in Fig 11. In the as-extruded state, the tensile strength was improved by additions of the alloying elements. Increases in aluminum and cadmium contents caused decreases in mechanical properties in specimens aged at 150°F for 48 hr. The effect of an increase in silver from 0 to 4 pct stabilized the mechanical properties for the same aging treatment. This stabilizing effect of silver on mechanical properties was noteworthy throughout the work on magnesium-lithium base alloys.

The independent effects of variations in magnesium-lithium ratio, zinc, cadmium, and silver, were studied in 36 quinary magnesium-lithium-zinc-cadmium-silver alloys by means of the factorial design technique. In Fig 12

FIG 9—Effect of zinc at different magnesium-lithium ratios on mechanical properties of extruded ternary alloys.

the average yield strengths of the alloys in the as-extruded state and after aging at 150°F for 48 hr are plotted as functions of the composition.

The yield strength of the alloys increased in the as-extruded condition as Mg/Li increased. Aging increased the yield strength of 6 Mg/Li alloys but decreased the yield strength of alloys of higher magnesium-lithium ratio.

Cadmium was similar in its effect in this series of alloys as in the previous series. It increased the yield strength of the alloys in the extruded condition but did not prevent the loss of yield strength upon aging at 150°F. The effects of zinc additions were similar to those produced by cadmium. An increase in silver from 4 to 6 pct had a stabilizing influence as shown by the fact that there was no decrease in yield strength after aging for 48 hr at 150°F.

The effects of aluminum in two series of 6 Mg/Li-aluminum-cadmium-silver alloys are shown in Fig 13. Excellent mechanical properties were obtained with 1 and 2 pct of aluminum in the alloys containing 4 pct silver. The alloys with 4 pct silver were less adversely affected by the 150°F aging treatment than were the alloys with 2 pct silver. As a point of interest, the alloys with 2 pct aluminum were less stable than were the alloys with 0.5 and 1 pct aluminum.

From the results obtained on 36 magnesium-lithium-zinc-cadmium-silver al-

FIG 10—Effect of variations in zinc, aluminum, or silver contents on the tensile properties of extruded 24 Mg/Li-Zn-Al-Ag alloys.

loys prepared according to a factorial design, it was possible to select a number of alloys whose tensile and yield strengths were increased by aging for 48 hr at 150°F. Their mechanical properties after the aging treatment are shown in Table 3. These results are indicative of the excellent mechanical properties which can be obtained in the magnesium-lithium base alloy system. It is noteworthy that these alloys, like

all high-lithium, magnesium-lithium base alloys, have equal compressive and tensile yield strengths and have high elastic limits in both tension and compression. Their notched impact strength, on the other hand, is rather low. The 8.1 Mg/Li alloy is included in this table for comparison purposes. The high-strength alloys of the 8.1 Mg/Li type show a considerably greater loss in strength during the

FIG 13—Effect of aluminum at two different silver levels on mechanical properties of a 6 Mg/Li-8 pct Cd base quinary alloy.

FIG 14—Effect of cadmium on mechanical properties of a 6 Mg/Li-1 pct Al-2 pct Ag alloy. (Aging treatment: 48 hr at 150°F.)

150°F aging treatment than do the alloys, listed in the table, of lower magnesium-lithium ratio.

The high-lithium, magnesium-lithium alloys were capable of dissolving cadmium in much larger amounts than the 6 pct generally added heretofore. Large amounts of cadmium, when substituted for the zinc or aluminum, not only produced high strength but enabled the alloys to retain this strength after aging at 150°F. As shown in Fig 14 and 15, the addition of 12 pct cadmium resulted in high strength which was not reduced by aging 48 hr at 150°F. However, alloys with 16 pct cadmium overaged and lost strength during the 48-hr treatment.

Continued investigation of high-cadmium-bearing alloys showed that, in the absence of zinc and aluminum, 16 pct cadmium could be added without causing overaging during the 48 hr at 150°F treatment. An alloy having the composition, 6 Mg/Li-16 pct cadmium-6 pct silver, was found to retain its high strength for over 1000 hr at 150°F. The mechanical properties of the alloy, after extruding and aging at 150°F for 48 hr, were as follows:

Tensile ultimate strength—48,000 psi
Tensile yield strength —47,000 psi
Elongation in 2 in. —2 pct

Although the ductility of this alloy was low, a slight modification of the composition to 15 pct cadmium and 5 pct silver increased the ductility considerably without seriously affecting the strength or the ability of the alloy

FIG 15—Effect of cadmium on mechanical properties of a 7 Mg/Li-2 pct Zn-4 pct Ag alloy. (Aging treatment: 48 hr at 150°F).

to retain its strength after a prolonged treatment at 150°F.

An extensive study of the fabricating characteristics and strength properties of the 6 Mg/Li-15 pct cadmium-5 pct silver alloy was also conducted. The alloy was easily forged and rolled at 400°F, and after a solution treatment, it could be cold rolled extensively. Its mechanical properties after extruding and aging at 150°F for 24 hr were as follows:

Tensile ultimate strength—46,000 psi
Tensile yield strength —43,000 psi
Elongation in 2 in. —8 pct
Reduction of area —8 pct
Hardness, Rockwell E —92

A stress-strain curve for the 6 Mg/Li-15 pct cadmium-5 pct silver alloy is shown in Fig 16. It is typical for the high-strength, magnesium-lithium base alloys and is characterized by a high elastic limit and a high compressive yield strength. Fig 17 and 18 show respective stress-strain curves for a commercial magnesium alloy and a commercial aluminum alloy. It will be noted that the curve for the magnesium-lithium alloy bears a greater resemblance to the curve for the aluminum alloy than it does to the curve for the magnesium alloy.

FIG 18—Tension-compression stress-strain curves for commercial aluminum alloy 14S-T.

COMPARISON OF STRUCTURAL CHARACTERISTICS OF MAGNESIUM-LITHIUM BASE ALLOYS WITH OTHER ENGINEERING MATERIALS

The magnesium-lithium base alloys by virtue of their low densities, 1.65 g per cc or less, have considerable advantage when compared to other structural materials on a strength-weight basis.

The strongest available commercial aluminum alloy has a yield strength of the order of 72,000 psi and a density of about 2.8 g per cc. For equivalent strength on a pound-for-pound basis, a magnesium-lithium base alloy, having a density of 1.55 g per cc, should have a yield strength, in compression and tension, of the order of 40,000 psi, while one having a density of 1.65 g per cc should possess a yield strength of about 42,500 psi. As shown in the preceding text, these yield strength values are exceeded in many magnesium-lithium base compositions.

The strength properties of two magnesium-lithium base alloys are compared with other commonly used structural alloys in Fig 19. The strength values representative of the various materials are those obtained

FIG 19—Comparison of strength properties of Mg-Li base alloys with those of other alloys.

fairly high modulus of elasticity (about 6,500,000 psi) of the magnesium-lithium base alloys make these alloys far superior, in this respect, to other structural materials.

Work-hardening Capacity and Stability of Magnesium-lithium Base Alloys

WORK-HARDENING CAPACITY

Early in the study of magnesium-lithium base alloys, it was found that most of the alloys being investigated were incapable of appreciable work hardening. There were a number of indications of the lack of work-hardening capacity, a few of which are enumerated as follows:

1. At rates of tensile loading comparable to those used for testing other materials, such as copper-base, iron-base, aluminum-base, or ordinary magnesium-base alloys, the yield strength of high-lithium, magnesium-lithium base alloys was found to be fictitiously high. The effect of the rate of loading on the yield strength of a few of the early magnesium-lithium base alloys is shown in Table 4. The first three alloys listed therein extended at a rapid rate under a tensile load near their apparent yield strength. The yield strength of the fourth alloy, which was low in lithium content, was not affected by the change in rate of loading.

2. The apparent yield strength of high-lithium, magnesium-lithium base alloys was not appreciably increased by cold stretching. The effect of a prior stretch of 5 and 10 pct on yield strength of four tensile bars is shown in Table 5.

Table 4 . . . Effect of Rate of Loading on the Tensile Yield Strength of a Series of Early Magnesium-lithium Base Alloys

| Mg/Li | Composition, Pct | | | | Yield Strength, psi | |
|-------|------------------|------|----|----|---------------------|---------------------|
| | Mg | Li | Zn | Al | Loaded, 0.02 ipm | Loaded, 0.00004 ipm |
| 9.7 | 87 | 9 | 4 | | 25,200 | 21,500 |
| 9.7 | 87.9 | 9.1 | 2 | 1 | 25,600 | 23,900 |
| 8.1 | 87.2 | 10.8 | 2 | 2 | 24,200 | 21,500 |
| 24 | 94.1 | 3.9 | | 2 | 23,000 | 23,000 |

Table 5 . . . Effect of Cold Stretching on the Tensile Yield Strength of a Series of Early Magnesium-lithium Base Alloys

| Mg/Li | Composition, Pct | | | | Yield Strength, psi | | |
|-------|------------------|------|----|----|---------------------|--------------------|---------------------|
| | Mg | Li | Zn | Al | 0 Pct Cold Stretch | 5 Pct Cold Stretch | 10 Pct Cold Stretch |
| 9.7 | 87 | 9 | 4 | | 25,200 | 25,600 | |
| 9.7 | 87.9 | 9.1 | 2 | 1 | 25,600 | 26,500 | 26,800 |
| 8.1 | 87.2 | 10.8 | 2 | 2 | 24,200 | 26,500 | |
| 24 | 94.1 | 3.9 | | 2 | 23,000 | 34,100 | |

In only the low-lithium alloy was a considerable increase effected in the apparent yield strength by a 5 pct prior stretch.

3. The apparent yield strength of 26,300 psi for an extruded alloy of 87 pct magnesium-9 pct lithium-4 pct zinc was not increased by cold-drawing reductions as high as 55.5 pct.

4. The apparent yield strength of 22,500 psi for a hot-rolled alloy of 87 pct magnesium-9 pct lithium-4 pct zinc could be increased only to 24,000 psi by a 75 pct cold-rolling reduction.

Thus the inability of the first magnesium-lithium base alloys investigated to work harden satisfactorily became readily apparent. The seriousness of this was more fully appreciated when a close relationship was found between the work-hardening characteristics and the stability of the mechanical properties at moderately elevated temperatures. In order to evaluate quickly a large number of compositions and to determine the effect of various addition elements on the work-hardening characteristics of the magnesium-lithium base, a modified test to determine work-hardening capacity was devised. A schematic drawing of the testing equipment is shown in Fig 21.

In this test, the specimens are supported on rails spaced 3 in. apart and loaded in the midpoint as a simple

FIG 20—Relative resistance to buckling of various structural alloys compared to that of 24S-T4 aluminum alloy.

beam. The deflections of the bars are measured at the time of loading and then at intervals over a period of a week. The bend-deflection values are plotted against the time elapsed after loading to obtain bend deflection-time curves. Such curves for alloys having good, fair, and poor work-hardening characteristics are shown in Fig 22. The total bend deflection within the 144-hr period of the test and the rate of deflection during the 120- to 144-hr period were used as a measure of the relative merit of the alloys. It will be noted from Fig 22 that deflection readings were taken for 168 hr, in order to obtain an accurate curve in the 120- to 144-hr interval.

Because the bend-deflection test procedure was used primarily to determine alloy additions which would improve work-hardening capacity, the bend tests were made, for the most part, on bars loaded in such a way that the extreme fiber stress exceeded the yield point of the material. The bend-deflection test was of little value for studying age-hardening alloys, because this type of alloy showed marked variations in behavior during the course of the test as a result of aging at room temperature.

Whereas the bend-deflection rate, as measured during the interval between 120 and 144 hr, is of interest and of value in assessing the work-hardening

FIG 21—Bend-deflection test apparatus for determining work hardenability.

characteristics of each composition, comparisons between various alloy compositions can be made most easily by examining the total bend deflection during the 0- to 144-hr interval. Results shown in Fig 23 reveal that the ability of a material to withstand bending loads which produce an extreme fiber stress greater than the yield strength apparently depends upon the work-hardening capacity of the material and not upon the yield strength. For example, pure magnesium, with a yield strength nearly twice that of pure aluminum, deflected nearly twice as much as aluminum in 144 hr when tested at an extreme fiber stress of 21,000 psi. It is apparent, from an examination of the 9 bars at the left of the diagram, that the first lithium additions tend to increase the yield strength and to reduce the total bend

FIG 22—Typical bend-deflection rate curves.

deflection markedly. Larger additions of lithium decreased the yield strength moderately, producing some increase in total bend deflection. This trend continued until a Mg/Li of 8 was reached. At this ratio, and continuing through 6 Mg/Li, the total deflection was high. Thus, with only a slight decrease in yield strength at these high lithium contents, a deflection of 0.2 in. was obtained in 24 hr.

The additions of 4 pct and 9 pct zinc to an alloy of 8 Mg/Li base increased the yield strength to 22,000 and 31,000 psi, respectively, and reduced the total bend deflection to 0.025 in. and 0.010 in., respectively. A 0.5 pct addition of aluminum to the 8 Mg/Li base was equally as effective as a 4 pct zinc addition in raising the yield strength of the material, but was far more effective in reducing the total bend deflection. A 6 pct aluminum addition was responsible for a still more pronounced increase in yield strength. On the other hand, 6 pct aluminum was inferior to 0.5 pct aluminum in reducing the total bend deflection. It is important to note that the zinc- and aluminum-bearing alloys were of the age-hardenable type, and for this reason, strict comparisons of the work-hardening capacities of such alloys, as measured by the bend-deflection test, were not possible.

The most outstanding effect of alloy additions was observed when 4 pct silver was added to an 8 Mg/Li or 6 Mg/Li alloy. The effect of silver is shown in Fig 23.

The mechanism by which an addition such as 4 pct silver or 0.5 pct aluminum improves the work-hardening capacity

of the magnesium-lithium alloy matrix is not entirely clear. It appears, however, that most additions having some solid solubility in the magnesium-lithium base at room temperature will effect some improvement in the work-hardening capacity.

In Table 6 are reported the total bend-deflection values for specimens of the four alloys previously noted in Tables 4 and 5. The total bend-deflection values of the first three alloys shown were high even though an extreme fiber stress of 21,000 psi was appreciably below the apparent yield strength of the alloys. An interesting observation made from results in Table 6 was that the second alloy, which showed some superiority in work-

Table 6 . . . Total Bend Deflection 144 Hr after Loading a Series of Early Magnesium-lithium Base Alloys

| Mg/Li | Composition, Pct | | | | Apparent Yield Strength, psi | Total Bend Deflection, ¹ Inch |

¹ Measured 144 hr after loading to an extreme fiber stress of 21,000 psi.

hardening capacity in Tables 4 and 5, also showed a slight superiority to the first and third alloys in resistance to bending. The bend-deflection value for the low-lithium alloy was markedly lower than the values for the three high-lithium alloys.

The bend-deflection test had certain advantages over the other possible methods for determining work-hardening capacity. It could be used to examine a large number of alloys at one time; specimen preparation was a simple matter; and perhaps of greatest importance, temperature was not a variable in the course of the test because it was readily conducted in a room kept at a constant temperature of 85°F.

The increase in hardness obtained by cold rolling a strip of the alloy to a reduction of 15 pct was also used as a measure of the effect of alloy additions on the work-hardening capacity of magnesium-lithium base compositions. It yielded some useful information and generally confirmed the results of the

FIG 23—Total bend deflection vs. tensile yield strength for various alloys.

bend-deflection test, but was not so sensitive as the bend-deflection method for revealing the effects of alloying elements. A work-hardening test based on hardness measurements has the objection that the hardness measurement itself depends to some extent on the work-hardening capacity of the material being tested. To determine the stability of work-hardened alloys, the cold-rolled specimens were held at temperatures of 150 and 225°F and their hardness measured at periodic intervals.

The bend-deflection test was also supplemented by the use of a tensile-creep test for the latter is a more sensitive method of determining plastic flow in the region of the yield strength than is the bend creep test. The alloy additions which improved work-hardening capacity, as measured by the bend-deflection test, also improved the tensile-creep characteristics of the alloy.

STABILITY

The properties of high-strength magnesium-lithium base alloys are stable at room temperature. However at 150°F the alloys average slowly, with the magnesium strength being maintained not longer than 1000 hr. The stability is lower at higher temperatures. One of the more important objectives of the present investigation was the improvement of stability of the alloys at 150°F and higher temperatures.

It was found early in the experimental work that alloy additions which improved the bend-deflection characteristics of an alloy also improved the stability of that alloy in the age-hardened state. Silver, which was shown in Fig 22 and 23 to be markedly beneficial, had the following typical effect on stability:

| Composition | As Extruded | | As Aged at 150°F for 48 Hr | |
|---|---------------------|-----------------|----------------------------|-----------------|
| | Yield Strength, psi | Elongation, Pct | Yield Strength, psi | Elongation, Pct |
| 8.1 Mg/Li-6 pct Cd-6 pct Zn..... | 35,800 | 20 | 24,400 | 36 |
| 8.1 Mg/Li-6 pct Cd-6 pct Zn-6 pct Ag..... | 32,700 | 26 | 34,600 | 26.5 |

Other examples of the effect of silver on the stability of mechanical properties were shown in previous figures.

When it was found that silver had an important effect upon the stability characteristics of age-hardened alloys, a considerable portion of the experi-

mental effort was directed to preparing various silver-containing alloy compositions and testing them after extruding, and after extruding and aging at 150°F for 48 hr. The mechanical properties of these alloys were discussed earlier in this paper.

One of the first alloys prepared that showed fairly good stability had the composition 7 Mg/Li-3 pct zinc-7 pct cadmium-3 pct silver. This alloy had the following properties:

| | Yield Strength, psi | Tensile Strength, psi | Elongation, Pct | Reduction of Area, Pct | Hardness, Rockwell E |
|---------------------------------|---------------------|-----------------------|-----------------|------------------------|----------------------|
| As extruded..... | 37,400 | 40,600 | 20 | 44 | 87 |
| As aged at 150°F for 48 hr..... | 35,500 | 39,400 | 28.5 | 43.3 | 88 |

Age-hardening curves for this alloy, at room temperature and at 150°F, are shown in Fig 24. It is apparent from an examination of the curve for 150°F that a reasonably high hardness was maintained for only about 100 hr. Thus, the fact that the mechanical properties after aging for 48 hr at 150°F were not appreciably changed from those obtained in the as-extruded state was no indication that the alloy was stable when held for extended periods at 150°F. It became the practice with subsequent alloys to determine the aging curves, hardness vs. time at temperature, as well as the mechanical properties after various conditions of aging.

Such hardness vs. time at temperature curves showed that an increase in the amount of lithium above that required to make the alloys 100 pct beta was beneficial because it improved the stability. In most alloys investigated, maximum stability was achieved at 6 Mg/Li; therefore, a large number of compositions having a magnesium-

lithium ratio of 6 were studied.

Although many elements were found which could cause precipitation in magnesium-lithium base alloys, it appeared that such precipitate-forming elements as silver, cadmium, aluminum, or zinc would be of major importance.

FIG 24—Age-hardening characteristics of the 7 Mg-Li-3 pct Zn-7 pct Cd-3 pct Ag alloy. (Specimens quenched from 475°F.)

Therefore, an investigation of the solubility limits of these elements in the

6 Mg/Li-base alloys was initiated. An indication of the solubility limit for an element was obtained by adding it in small but increasing increments to a magnesium-lithium base, then solution treating the alloys by quenching from 500°F, and finally determining their change in hardness with time at 150°F. The maximum hardness values obtained upon aging are plotted in Fig 25. The apparent effective solubility limits at 150°F for the four elements in the beta-phase alloys of 6 Mg/Li base were roughly 8 pct silver, 12 pct cadmium, 0.5 pct aluminum, and 1.5 pct zinc.

Investigations of this type were also conducted at other ratios of magnesium to lithium. In the beta phase, the solubility at room or at slightly elevated temperatures of almost every element increased as the lithium content increased. For example, at 8.1 Mg/Li, the maximum amount of cadmium that appeared soluble was 6 pct; at 6 Mg/Li, about 12 pct was soluble; and at 5 Mg/Li, over 16 pct was soluble. Silver seemed to be an exception. At 8.1 Mg/Li, over 12 pct silver was soluble; at 6 Mg/Li, only about 8 pct appeared to be soluble; while at 5 Mg/Li, less than 4 pct appeared to be soluble.

In order to determine their effects in age hardening, a large number of elements were added in various concentrations to a 6 Mg/Li-4 pct cadmium-6 pct silver base. The results of this study are shown in Table 7. Although many concentrations of each of the elements shown were studied, only that concentration is reported which had the greatest stabilizing effect on the alloy. It is interesting to note that many additions formed precipitates which were visible under the microscope yet did not cause age hardening.

¹ Other elements investigated included Te, Be, P, Bi, Mn, B, and Co, but these were not recovered in the alloys.

² With the exception of these elements, chemical analysis generally showed good recovery of all components.

The effects at 150°F of various quantities of aluminum on the aging characteristics of the 6 Mg/Li-4 pct cadmium-6 pct silver-base alloy, as shown in the age-hardening curves of Fig 26, were particularly interesting. As the aluminum content of the alloy was increased to 6 pct, there was a continuous increase in the maximum hardness obtained by aging. The time at maximum hardness, however, decreased as the aluminum content increased.

A large number of magnesium-lithium, high-cadmium, high-silver alloys were also studied. It was found that the alloys with 6 Mg/Li-12 pct cadmium-8 pct silver-0.5 pct aluminum, and with 6 Mg/Li-16 pct cadmium-6 pct silver, when quenched from 500°F and aged at 150°F, hardened appreciably and maintained their high hardness for a considerable length of time when held at that temperature. The aging characteristics of the two alloys are shown in Fig 27. As noted previously, neither of these alloys had as high ductility as was desired. A slight modification in composition of the alloys from 6 Mg/Li-16 pct cadmium-6 pct silver to 6 Mg/Li-15 pct cadmium-5 pct silver improved the ductility considerably. The aging curve for the latter alloy is shown in Fig 28. The alloy, solution treated to a Rock-

material is about 43,000 psi and the elongation is about 8 pct.

The stability of magnesium-lithium base alloys may be improved by solution treatment. Alloys aged from the hot- or cold-rolled states usually contain residual stresses so that the rate of precipitation is increased and hence stability impaired.

Although the work-hardening capacity and the stability of magnesium-lithium alloys are not yet as desired, nevertheless considerable improvement has been made in these characteristics. It is of interest that the all-alpha phase magnesium-lithium alloys studied were quite capable of work hardening and their mechanical properties at ordinary temperatures were reasonably stable.

Corrosion Resistance

At the inception of the research program, it was expected that the addition of considerable percentages of lithium to magnesium would affect the corrosion resistance adversely. The experimental program was conducted on the premise that, if magnesium-lithium base alloys of satisfactory mechanical properties were developed, a method of protecting them from corrosion by cladding or by the use of paints, lacquers, and varnishes could be effected.

Early in the program, it was found that binary alloys containing about 11 pct lithium were remarkably good in their resistance to corrosion. This was demonstrated by results in Fig 29 which show the corrosive effect of alternate immersion in a 3 pct sodium chloride solution upon a series of magnesium-lithium base alloys. A speci-

men of ASTM No. M-1 magnesium-base alloy, the most corrosion resistant of the commercial alloys, was used for comparison. The immersion cycle was standardized at one-half minute in the solution and two minutes out, the temperature of the solution being maintained at 95°F. The corrosion rates of these alloys are given in Table 8.

It is apparent from the data that the binary magnesium-11 pct lithium alloy (Mg/Li = 8.1) is as resistant to corrosion, at least under the conditions of the test used, as the commercial alloy, ASTM No. M-1.

Results of corrosion tests on a series of magnesium-lithium-zinc-cadmium-silver alloys in a 3 pct sodium chloride solution are shown in Table 9. For comparison purposes, a magnesium-lithium binary alloy, a magnesium-lithium ternary alloy containing 4 pct zinc, and three commercial magnesium-base alloys were also tested. The resistance to corrosion of the magnesium-lithium base complex alloys decreased with an increase in the combined zinc and silver contents, as shown in Fig 30.

Preliminary tests showed that the 6 Mg/Li-15 pct cadmium-5 pct silver alloy also had poor corrosion characteristics. Its resistance to corrosion might be improved by cladding with a more corrosion-resistant material, such as the 8.1 Mg/Li binary alloy or pure aluminum. To give maximum protection, the cladding material should be anodic to the base material. Hence, solution potential measurements were made in a 3 pct sodium chloride solution on the 6 Mg/Li-15 pct cadmium-5 pct silver alloy, on the 8.1 Mg/Li binary alloy, and on 2S aluminum. The results obtained are shown in Fig 31.

It was evident from the data that the 8.1 Mg/Li binary alloy was anodic to the high-strength alloy and, thus, would be expected to offer galvanic protection. On the other hand, 2S aluminum was found to be cathodic to the high-strength alloy and could be expected to afford only mechanical protection.

The 6 Mg/Li-15 pct cadmium-5 pct silver alloy can be clad either with the 8.1 Mg/Li binary alloy or with commercially pure aluminum. To obtain a bond between the materials used in cladding, sheets of the materials assembled in packs were tack welded at the edges and then rolled at temperatures above 600°F. Microscopical examination of the interface between the strong alloy in the core and the 8.1 Mg/Li binary alloy at the surface of the clad structure showed that actual welding had occurred in the process. On the other hand, the interface between the strong alloy in the core and 2S aluminum showed the existence of a thin layer of brittle, intermetallic com-

pounds. For the clad structures in the as-rolled condition, these compounds were not deleterious; but after prolonged heating at 400°F, the intermetallic layer failed, causing the aluminum to separate from the magnesium-lithium base alloy.

The results of a series of corrosion tests made on the clad alloys are shown in Table 10. It appears that the corrosion resistance of the 6 Mg/Li-15 pct cadmium-5 pct silver alloy clad with the 8.1 Mg/Li binary was fairly good, although it did not quite equal that of the commercial magnesium-base alloys, AZ61X or MI. Painting of the cut edges of the clad material was especially effective in reducing corrosion in the simulated marine atmosphere. Cladding with 2S aluminum was advantageous where the edges of the core alloy were protected by paint.

In order to determine the extent of anodic protection offered by the 8.1 Mg/Li cladding on the 6 Mg/Li-15 pct cadmium-5 pct silver alloy, a number of specimens were tested on which a

FIG 30—Effect of silver and zinc on corrosion resistance of Mg-Li alloys in salt water.

$\frac{1}{16}$ - to $\frac{1}{4}$ -in. wide strip of the cladding was removed by machining to expose the core material. These specimens were tested in aerated 3 pct sodium chloride and aerated synthetic sea water. As shown in Fig 32, the binary alloy cladding afforded protection to the exposed base alloy when a strip as wide as $\frac{1}{8}$ in. of the base alloy was exposed. These experiments were in agreement with the solution potential measurements reported in Fig 31.

Metallography

A considerable amount of work in connection with microstructural examinations and X ray diffraction studies was conducted on the magnesium-lithium base alloys. In agreement with work of other investigators, it was shown that the beta-phase solid solution had a body-centered-cubic lattice similar to that of lithium. The beta phase was obtained when additions of 10.5 pct of lithium or more were made to magnesium. No attempts were made to establish with any degree of accuracy the exact location of the boundary between the alpha plus beta and the beta-phase regions which, according to the literature, exists at about 10.3 pct lithium.

The ternary Mg-Li-Zn, Mg-Li-Cd, Mg-Li-Al, and Mg-Li-Ag alloys having sufficient lithium to consist of beta solid solution and a sufficient quantity of the third element, may contain a precipitate which has been termed theta. From X ray diffraction studies, theta has been assigned the tentative composition $MgLi \cdot LiX$ where X represents any of the elements zinc, cadmium, aluminum, silver, indium, or thallium. The lattice parameter of the theta phase has a value of about 6.92 Å in the cadmium-bearing alloys, a value of from 6.66 to 6.68 Å in the zinc-bearing alloys, a value of 6.72 Å

in the aluminum-bearing alloys, and a value of 6.78 Å in the silver-bearing alloys. The latter value is in fairly close agreement with the theoretical value of 6.81 Å calculated for MgLi · LiAg.

Partial solution of the theta phase appeared to begin in the neighborhood of 300°F, and complete solution of the theta phase in most of the experimental alloys was evident at temperatures of the order of 450 to 550°F. The experimental alloys for the most part contained relatively small amounts of theta-forming elements, and none of the alloys susceptible to aging contained excessively large amounts of theta. In the Mg-Li-Ag alloys, the lattice parameter of the theta phase was observed to change as aging progressed at 150°F. The highest experimental value obtained was 6.78 Å, but this decreased to 6.70 Å after a long time at 150°F. A similar change in the lattice parameter of the theta phase was also observed in the Mg-Li-Zn and Mg-Li-Cd alloys. Such variations in lattice parameter may indicate that the theoretical structure MgLi · LiX, heretofore assigned to theta, is a transition structure which changes on prolonged aging. Another possible explanation, discussed later in this paper, is that theta only approximates the composition MgLi · LiX and that it may have appreciable quantities of lithium in solution. Attempts to determine the cause of the changes in lattice parameters are planned for later study.

In addition to the theta phase, LiAl has been found in the Mg-Li-Al alloys. Since most of the experimental effort has been devoted to low-aluminum-bearing alloys, and since this phase appears to be more prevalent in the higher aluminum alloys, no specific information about its occurrence has been obtained. It has been observed, however, that LiAl is soluble in the matrix at high temperatures and can be precipitated at low temperatures. Its occurrence has been identified in 8.1 Mg/Li alloys containing as little as 2 pct aluminum after aging at 150°F. Moderate quantities of LiAl occur at 6 pct aluminum and large quantities at 12 pct aluminum, the quantities increasing at both aluminum contents with reduction in lithium content.

In the Mg-Li-Cd alloys, when additions of cadmium were up to 12 pct, an unidentified phase was observed. Although the phase was not identified, it was established that it was neither Mg₃Cd nor LiCd.

The occurrence of the theta phase

FIG 31—Time-potential values for magnesium-lithium alloys compared with aluminum, 3 pct NaCl solution at 95°F.

and lithium-bearing compounds in ternary alloys is associated with a tendency toward the formation of the alpha phase. Theta and the lithium-bearing compounds appear to remove some lithium from the matrix so that alpha can form in their immediate vicinity. The association of the alpha phase with theta is shown in Fig 33, where a precipitation pattern of theta and alpha occurs in a pearlitic-like structure in the beta background. Fig 34 shows the same type of pearlitic structure after long-time aging, the white material in this case being the alpha phase. This is evidence that theta can absorb sufficient lithium from the magnesium-lithium solid solution to

produce an alloy of predominantly alpha phase, and is probably best explained by considering theta to be a phase in which large quantities of lithium are soluble.

The mode of precipitation of the theta phase in magnesium-lithium base alloys was of interest. A Mg-Zn-Cd-Ag alloy extruded at a temperature sufficiently low to produce some cold working is shown in Fig 35. This alloy was aged 48 hr at 150°F. It is apparent from the micrograph that the precipitated theta phase is concentrated within the cold-worked grains. The same structure at a higher magnification is shown in Fig 36. The strength and ductility of alloys in which precipitation occurs

in the cold-worked grains are higher than for alloys which are solution treated wherein the grains are equiaxed and where precipitation occurs only at grain boundaries.

Summary and Conclusions

The hexagonal, close-packed crystal lattice of magnesium can be converted to the body-centered-cubic lattice of

lithium by an addition of about 10.3 pct by weight or more of lithium. Additions of lithium of between 5.7 and 10.3 pct produce a structure which is a mixture of lithium dissolved in alpha, hexagonal magnesium, and magnesium dissolved in beta, body-centered-cubic lithium.

The conversion of the crystal lattice from hexagonal to body-centered cubic improves many of the properties of magnesium. Some of these improvements are:

1. Increased ratio of compressive to tensile yield strength; the compressive yield strengths of beta-phase magnesium-lithium base alloys equal or surpass the tensile yield strengths.
2. Increased modulus of elasticity in compression so that the compressive modulus equals the tensile modulus.
3. Improved formability at room temperature.
4. Improved hot- and cold-rolling and extrusion characteristics.

Because of these improvements, a major portion of the experimental work was devoted to the study of the single-phase beta alloys. Considerable attention was also given to the single-phase, lithium-bearing alpha magnesium alloys and the two-phase alloys, since these alloys have certain advantages over magnesium, such as improved working characteristics, but have lower cost than the higher lithium alloys.

The melting of magnesium-lithium alloys is no more difficult than the melting of ordinary magnesium, provided certain precautions are followed. The alloys are generally melted in a steel crucible under an argon atmosphere or lithium chloride-lithium fluoride flux, or a combination of both. They can be poured in air without protection. Cast iron, or graphite ingot molds are quite satisfactory, but they should be dried before they are used.

The magnesium-lithium alloys can be hot worked with ease at temperatures of the order of 450°F. They can be cold rolled without difficulty and total reductions of 50 pct are common for most compositions. Many of the magnesium-lithium base alloys can be cold drawn. However, some difficulty is encountered when starting the cold-drawing operation because the alloys do not work harden well and tips formed on the ends of bars are not sufficiently strengthened to withstand the stresses necessary to start the bar through the die.

Magnesium-lithium base alloys hav-

ing good mechanical properties invariably possess hardnesses of the order of 85 Brinell. High-strength magnesium-lithium base alloys have been developed which have densities of the order of 1.45 to 1.65 g per cc, compared with a density of 1.8 g per cc for present magnesium-base alloys and about 2.8 for aluminum-base alloys. Since yield strengths of approximately 40,000 to 45,000 psi can be obtained with these alloys, they compare favorably on a strength-weight basis with the strongest available commercial aluminum-base alloy, 75ST.

The modulus of elasticity of magnesium-lithium base alloys varies slightly with composition; however, the alloys possess an average value of about 6,500,000 psi, which is the same in tension and compression. This value compares favorably with that for the commercial magnesium-base alloys. Because of the low density of the magnesium-lithium alloys, it can be shown that their resistance to buckling during compressive loading is better than for equivalent weights of commercial magnesium-base alloys or other available commercial structural alloys.

Two characteristics of the magnesium-lithium base alloys containing the body-centered-cubic phase which have been found to be closely interrelated are poor work-hardening capacities and lack of stability of mechanical properties in the age-hardened state. A simple bend-deflection test, in which alloy specimens were loaded above the yield stress, was developed to determine which alloy addition improved the work-hardening characteristics. This test is described in detail. Those alloy additions which were most effective in improving work-hardening characteristics were also very beneficial in improving stability of mechanical properties. The degree of stability was determined by comparing curves showing the relationship of hardness to aging time at 150°F.

By means of these tests, it was found that the addition of silver to the alloys was most effective both in improving the work-hardening capacity of the alloys and in stabilizing the mechanical properties of age-hardened alloys. However, although great progress has been made in improving these characteristics, they are not yet entirely satisfactory.

One of the best alloys developed thus far, from the standpoint of stability, has a composition of 68.5 pct magnesium, 11.5 pct lithium, 15 pct

cadmium, and 5 pct silver. Its yield strength of 43,000 psi and its elongation of about 8 pct can be maintained at a temperature of 150°F for an extended period.

The corrosion resistance of most magnesium-lithium base alloys, especially those containing large quantities of zinc, silver, and/or cadmium is poor; however, it was observed that the magnesium-lithium binary alloy containing about 11 pct lithium had good corrosion resistance. This material can

be used to clad and to protect anodically many of the higher strength alloys.

The magnesium-lithium base alloys containing zinc, aluminum, cadmium, and/or silver can be hardened by the precipitation of a phase, called theta, which was assigned the tentative formula $MgLi \cdot LiX$ where X may be any one of the elements zinc, aluminum, cadmium, or silver. The lattice parameter of theta phase varies slightly with composition and aging time. It was

concluded tentatively that the theta phase is a transition structure in which large quantities of lithium are soluble.

Future research on magnesium-lithium alloys will undoubtedly be concerned with improvements in stability, work-hardening capacity, and corrosion characteristics, and with efforts to employ alloying elements which are relatively inexpensive and plentiful.

Acknowledgments

The experimental work discussed herein was conducted under the sponsorship of the Mathieson Chemical Corporation and the Navy Department, Bureau of Aeronautics. Considerable assistance in planning the work was received from individuals representing the sponsors. These men

included Messrs. R. E. Gage, and M. C. Taylor, from Mathieson Chemical Corporation; and Capt. J. E. Sullivan, Messrs. N. E. Promisel, and H. J. Boertzel, of the Navy.

Considerable assistance was received at Battelle from the following: Messrs. E. C. Kron and A. H. Hesse, who supervised and conducted much of the early work and made valuable discoveries and contributions; Dr. C. M. Schwartz and Mr. J. R. Doig, who conducted X ray diffraction studies; and Messrs. A. R. Elsea, and J. L. Stevens, who did the microscopical work. The assistance of Messrs. R. S. Springer, H. S. Sanders, C. R. Owens, R. V. Whittenberg, and T. C. Kronfoth, in the preparation and testing of the various melts is gratefully appreciated. Many others have made valuable contributions to the work, and while no specific acknowledgment is made to them herein, their part in this work is recognized.

Self-diffusion in Sintering of Metallic Particles

G. C. KUCZYNSKI,* Member AIME

Two particles in mutual contact form a system which is not in thermodynamical equilibrium, because its total surface free energy is not a minimum. If such a system is left for a certain period of time, the bonding of the two particles will take place in order to decrease the total surface area, even though the temperature is lower than the melting point. This phenomenon of bonding of two or more particles with the application of heat only and at temperatures below melting point of any component of the system will be called sintering, although the powder metallurgists use this term in a broader sense, including the presence of molten phase and pressure. It is the objective of this paper to study this process and the mechanisms involved in it.

This problem is of utmost importance to powder metallurgy and powder ceramics, and its technological aspects have been studied for a good many years. However, the powder metallurgical operations are too complex and include too many superimposing mechanisms, and too many variables for a direct study. It was therefore advisable for the purposes of this study to reduce the variables to a minimum. In this work the radius of the interface formed during bonding in a simple system composed of a spherical particle and a large block of the same metal was studied as a function of time and temperature. It is believed that the mechanism involved in this simple process is fundamental to any sintering operations.

Previous Work

J. Frenkel¹ was the first to make a serious attempt to develop a theory of sintering. He assumed that the process

FIG 1—Schematic representation of the cross-section of a spherical particle sintered to a metallic block.

consists of a slow deformation of crystalline particles under the influence of surface tension which reduces to a viscous flow where the coefficient of viscosity η is related to the self-diffusion coefficient D by the following equation

$$\frac{1}{\eta} = \frac{D\delta}{kT} \quad [1]$$

where δ is interatomic distance, k the Boltzman constant, and T the absolute temperature. This type of viscous flow of a crystalline substance is essentially different from the ordinary plastic flow. The latter is a specific property of crystals and cannot take place in amorphous bodies. According to Frenkel this viscous type of flow is due

to the diffusion of the holes or vacancies arising in the lattice. He was able to derive an equation relating the growth of the interface between two spherical crystalline particles or between a particle and a semi-infinite crystal (Fig 1) to time t at constant temperature. This relationship can be written as follows:

$$x^2 = \frac{3}{2} \frac{a\sigma}{\eta} t \quad [2]$$

where x is the radius of the interface assumed to be circular, a the original radius of the sphere and σ surface tension of the material. The other assumptions are that $\frac{x}{a}$ is less than 0.3 and that during the period t the original radius, a , of the metallic particle did not change appreciably.

A. J. Shaler and J. Wulff² followed closely the ideas of Frenkel in their theory of sintering of a mass of metallic powder. Neither Frenkel nor Shaler has validated his theoretical speculations with conclusive experimental data. Two measurements reported by

San Francisco Meeting, February 1949.

FIG 2—Copper particles sintered to copper blocks. *a.* At 700°C for 4 hr, 800 X. *b.* At 800°C for 2 hr, 900 X. *c.* At 900°C for 1 hr, 1000 X. *d.* At 1000°C for 0.5 hr, 600 X.

Shaler for copper powder sintered at 850 and 900°C yielded a value for the heat of activation of self-diffusion in copper which was 10 pct higher than those obtained by other methods. This is by no means an adequate test of the theory. In the first place two such measurements are not sufficient for evaluating the coefficient of self-diffusion D . More important, however, is the fact that the temperature dependence is of secondary importance only. The final check of this theory will come from the experimental investigations of the time relationships such as [2] above as will be shown later.

B. Ya. Pines³ developed a theory of sintering of the powder compacts based upon different assumptions. According to him the atoms from the surface of the compact migrate by diffusion to the internal voids filling them gradually, or, as Pines puts it, by moving the voids out from the body. This mechanism is essentially different from that postulated by Frenkel. The difference is that

while Pines visualizes sintering as filling of the voids atom by atom, Frenkel envisions them filled by slow viscous creep of the crystal. The conclusions arrived at by Pines are only of qualitative nature and do not render themselves for experimental verification.

Theoretical Considerations

Formation of the common interface between two particles or a particle and a crystal block can be achieved by one, or a combination of, the following mechanisms: viscous or plastic flow, evaporation and condensation, volume diffusion and surface diffusion.

As the objective of this paper is to determine experimentally which of these mechanisms are involved in sintering of the particles it is important to discuss briefly each of these in order to find out what kind of relationships characteristic for each mecha-

nism could be established and tested experimentally.

VISCOUS OR PLASTIC FLOW

This mechanism has already been discussed in connection with Frenkel's paper.¹ If only mechanism of viscous flow were responsible for sintering, the relationship between the radius of the interface and the time of heating at a given temperature would be expressed by Eq 2. A similar expression could be derived for plastic flow with only a different temperature dependent coefficient at variable t .

EVAPORATION AND CONDENSATION

According to the kinetic theory the rate G of evaporation of a gas from a surface above which the equilibrium pressure is p_1 , and the rate of condensation on a neighboring surface of pressure p_2 is

$G = K(p_1 - p_2)$ [3]
 where K is a function of temperature only. The equilibrium pressures are related to the respective radii of curvature. In our case ρ is the radius of the area of condensation and a the radius of the area of evaporation by the well known Kelvin equation:

$$\ln \frac{p_2}{p_1} = \frac{-2\sigma\delta^3}{kT} \left(\frac{1}{\rho} + \frac{1}{a} \right) \quad [4]$$

where σ is the surface tension of the body.

As $\rho \ll a$, $p_2 = p_1 - \Delta p$ and $\frac{\Delta p}{p_1}$ is small, Eq 3 can be written as follows:

$$G = \frac{K'}{\rho} \quad [5]$$

where K' is a function of temperature and p_1 only. In our problem (Fig 1) p_1 can be regarded constant because the radius of the sphere does not change appreciably. The radius of curvature ρ can be approximated as a function of x as follows: From Fig 1, it is obvious that

$$\rho = a(1 - \cos \theta) \text{ or } \rho = 2a \sin^2 \frac{\theta}{2}$$

as θ is very small and equal to $\frac{x}{a}$,

$$\rho = \frac{x^2}{2a}$$

Introducing this value for ρ in [5] we obtain

$$G = \frac{K''}{x^2}$$

The rate of condensation G on the area A of the junction between the particle and the crystalline block should be equal to the rate of mass transport which in turn is proportional to the rate of change of volume of the junction. We can write then

$$AG = \beta \frac{dv}{dt}$$

where β is independent of time.

But $A \cong \pi \frac{x^2}{a}$ and $V \cong \pi \frac{x^3}{2a}$ so

$$\frac{K''}{2\beta} = x^2 \frac{dx}{dt}$$

and after integration

$$x^3 = \frac{3}{2} \frac{K''}{\beta} t \quad [6]$$

In other words if the mechanism of evaporation and condensation were responsible for the formation of interface between particles, the radius of the junction should grow with such a rate that its cube would be proportional to time.

VOLUME DIFFUSION

If we assume the vacancy theory of diffusion, then the area near the

interface should have higher hole concentration than the remaining body of the particle. This is due to the fact that near the interface, where the radius of curvature is small the surface energy is very high and it can be lowered by decreasing the surface area. The decrease in surface area is produced by an increase in the interface volume which is accomplished by a larger concentration of vacancies present in that region. If the interstitial

atom mechanism is assumed, the junction area should be deprived of the interstitial atoms in order to decrease the total surface. This causes the flow of atoms from the other parts of our system to the junction. The third possible mechanism of diffusion known as atom exchange mechanism and sometimes considered possible^{4,13} is automatically eliminated if the actual sintering is caused by diffusion because in this case no concentration gradient

FIG 3—Silver particles sintered to silver blocks. 200 \times . *a.* (above) At 800°C for 24 hr. *b.* (below) At 900°C for 2 hr.

FIG 4—Logarithm of the ratio of the interface radius x to the radius of a copper particle sintered at indicated temperatures, plotted against the logarithm of sintering period t . The numbers at the points express time of heating in hours.

would be present. It is convenient to assume that the hole mechanism is the actual mechanism prevailing in self-diffusion of metals. In such a case, the surface forces tending to decrease the total surface area will build a high concentration of holes³ underneath the surface of the junction between the particle and the crystal block. This increment of concentration ΔC can be calculated from Kelvin's Eq 4

$$\Delta C = \frac{2\sigma\delta^3}{kT} \left(\frac{1}{\rho} - \frac{1}{x} \right) C$$

where C is the equilibrium concentration of the holes equal to $e^{-\frac{E}{RT}}$, E being the energy required to produce such a hole in the lattice. As $x \gg \rho$ the last equation can be written in the following form

$$\Delta C = \frac{2\sigma\delta^3}{\rho kT} e^{-\frac{E}{RT}}$$

As the concentration gradient is approximately equal to $\frac{\Delta C}{\rho}$, we can write the Fick's equation for our case

$$A \frac{\Delta C}{\rho} D' = \frac{dV}{dt} \quad [7]$$

where $\rho \cong \frac{x^2}{2a}$, $A \cong \pi \frac{x^3}{a}$ and $V \cong \pi \frac{x^4}{2a}$ as before and D' the coefficient of holes diffusion which obviously fulfills

the following equation $D' e^{-\frac{E}{RT}} = D_v$, where D_v is the coefficient of volume self-diffusion for a given metal. Introducing all these values into Eq 7 and integrating, we obtain

$$\frac{x^5}{a^2} = \frac{40\sigma\delta^3}{kT} D_v t \quad [8]$$

or in other words if the mechanism of diffusion was responsible for sintering, the fifth power of the interface radius is proportional to time.

SURFACE DIFFUSION

Very similarly we shall obtain the relation between radius x and time t in case the prevailing mechanism is surface diffusion. We have to put only $A \cong 2\pi\delta$ with concentration gradient

and volume rate the same as in the case of volume diffusion.

Integrating the differential equation resulting from Fick's equation we obtain

$$\frac{x^7}{a^3} = \frac{56\sigma\delta^4}{kT} D_s t \quad [9]$$

where D_s is the coefficient of surface diffusion.

Summing up we can tabulate the relationships between radius x of the interface formed during sintering between two particles and time t . These relations are as follows:

| | |
|------------------------------|--------------|
| Viscous or plastic flow | $x^2 \sim t$ |
| Evaporation and condensation | $x^3 \sim t$ |
| Volume diffusion | $x^5 \sim t$ |
| Surface diffusion | $x^7 \sim t$ |

The experiments described in the next paragraph were carried out in order to decide which mechanism or mechanisms actually prevail during sintering.

Experimental Method

In order to study experimentally the

relationship between the radius of the interface as a function of time and temperature it is necessary to measure this radius directly if possible. This was achieved by a very simple although somewhat laborious method. The metallic particles of spherical shape were dispersed on a flat block of the same metal, heated in a controlled atmosphere (hydrogen in the case of copper, hydrogen or air in the case of silver) at different temperatures and for various periods of time. After heating, the blocks with the particles sintered to them were mounted in bakelite and cut, in order to obtain a diametral cross-section of the particle in contact with the block. This cross-section was then examined under the microscope. The diameters of the particles and their interfaces with the blocks were readily measured with the microscope eyepiece micrometer. In order to assure the greatest accuracy of these measurements, the specimens were successfully polished down and after each of such operations readings of the radius of the interface for each particle were taken until a maximum radius was obtained.

The metals used in these experiments were copper and silver. The copper was round, atomized powder obtained from Greenback Industries, Inc. The shape of the powder particles was nearly

spherical as can be seen from Fig 2, *a*, *b*, *c*, and *d*. The diameters of these particles ranged from 4 to 100 μ . The powder was fractionated by the elutriation method into three lots. The first lot contained particles greater than 35 μ in diameter. The second particles between 15–35 μ and the third, particles less than 15 μ . The silver used was coarse atomized powder of about 350 μ in diameter furnished by Stevens Institute of Technology. This powder consisted of almost perfectly spherical particles as can be ascertained from Fig 3, *a* and *b*. The copper powder contained some oxygen so it was reduced by packing it in carbon and heating in a hydrogen atmosphere at 900°C for 18–24 hr. The resulting powder developed some blow holes. The copper blocks were cast of oxygen free high conductivity copper, the silver was spectroscopically pure. Their surfaces were thoroughly polished and cleaned by etching before the powders were dispersed on them. The copper was etched with ammonium hydroxide plus hydrogen peroxide and the silver specimens with potassium dichromate. After heating, the specimens were plated with nickel in order to avoid loosening or deforming the interfaces during the subsequent metallographic operations.

At least ten particles were measured for each temperature or time period. Some micrographs of the observed particles sintered to the metallic blocks are shown in Fig 2, *a*, *b*, *c*, and *d* and Fig 3, *a* and *b*.

Very fine copper particles (less than 10 μ) in diameter were not as round as the coarse ones and consequently yielded more scattered results. Also, it was impossible to polish down these particles, in order to obtain the maximum radius of their interface. Consequently a large number of them were

FIG 5—Logarithm of the ratio of the interface radius x to the radius a of silver particles sintered at indicated temperatures, plotted against the logarithm of sintering period t . The numbers at the points express time of heating in hours.

measured and only the largest values of radii were used for future calculations.

Results

Tables 1 and 2 contain the results obtained from measurements of the interface radii of copper and silver particles heated to different temperatures for various periods of time.

In the first and second columns of these tables, the temperature in degrees centigrade and time in hours are listed. The third and fourth column contain the observed radii of the interface and of the particle respectively (in centimeters). In the fifth column the ratios of these radii are given. The $\log \frac{x}{a}$ versus $\log t$ plots are given in Fig 4 and 5. The points fall on the straight lines whose inverse slope n is approximately equal to 5, as can be seen from the sixth volume of tables where the n values are listed.

The numbers at each point express the length of time in hours, for which a given specimen was heated.

The value 5 of the inverse slope n of the $\log \frac{x}{a} / \log t$ plot indicates that

within the range of temperatures, periods of time and particle size, used in this work and listed in Tables 1 and 2, the predominant mechanism of sintering is volume diffusion in agreement with Eq 8. This last equation permits us to evaluate the coefficient of volume diffusion D_v for each temperature provided that the interface radius is known. There is uncertainty in the value of the surface tension of copper and silver as they have not been determined experimentally for solid metals. In this work the values of surface tension as measured for molten metals were adopted, based on the assumption that they should be close to those for solids. The error introduced by this choice would not change the order of

magnitude of the coefficient of diffusion, calculated from Eq 8. Thus, for copper $\sigma = 1200$ ergs per cm^2 and for silver $\sigma = 1000$ ergs per cm^2 was used.⁵ The values of D_v for copper and silver are listed in Tables 3 and 4 respectively, along with temperatures and periods of heating time, radii of the particles and interfaces.

D_v was plotted on the semi-logarithmic scale against $\frac{1000}{T}$. T being absolute temperature. For large particles of 40μ or more in diameter straight lines were obtained as shown in Fig 6 and 7.

The heats of activation of volume diffusion, Q_v , and frequency factors, D_v^0 , were determined from these graphs. Thus for copper Q_v is 56000 cal per mol and $D_v^0 = 70 \frac{\text{cm}^2}{\text{sec}}$ and for silver $Q_v = 42000$ cal per mol and $D_v^0 = 0.6 \frac{\text{cm}^2}{\text{sec}}$. These values are in good

FIG 6—Variation of volume self-diffusion coefficient of copper with temperature as determined from sintering experiments. Logarithm of D_v vs. reciprocal of absolute temperatures.

agreement with those obtained by various workers who used the radioactive tracer method as is shown in Table 6. This suggests that the above described method may successfully be used for determination of the coefficient of self-diffusion of metals without using radioactive tracers. As it is difficult to get a perfectly round metallic particle it is more convenient to use wires and measure their rate of sintering to metallic blocks.*

Fig 6 shows that the coefficients of volume diffusion calculated from the rates of interface growth for small particles, (less than 30μ in diameter) when plotted on the semi-logarithmic

scale versus $\frac{1}{T}$ at lower temperatures

show deviations from the straight line although they fall on this line at higher temperatures; the smaller the particles the greater the deviations. These deviations are due to the surface diffusion mechanism predominant at lower temperatures and for smaller particles as will be proven later. In cases where both mechanisms, volume and surface diffusion, take place, the flow equation will be as follows:

$$\frac{dV}{dt} = n f_v + m f_s \quad [10]$$

n and m are fractions of the overall contributing flow, functions of x and a and obviously fulfill the relationship $n + m = 1$. From Eq 8 and 9 f_v and

f_s are easily calculated their values being as follows:

$$f_v = \frac{16\pi a \sigma \delta^3}{k T x} D_v$$

$$f_s = \frac{16\pi a^2 \sigma \delta^4}{k T x^3} D_s$$

Substituting these values as f_v and f_s into Eq 10, we obtain

$$\frac{dx}{dt} = \frac{8a^2 \sigma \delta^3}{k T x^4} \left(n D_v + m \frac{a}{x^2} D_s \right),$$

since $V \cong \frac{x^4}{2a}$ [11]

When the contact area, or the radius x , is very small one should expect that the contribution of flow due to surface diffusion will be overwhelmingly greater than that due to volume diffusion especially as $D_s > D_v$. In such cases also $m \cong 1$ and Eq 11 reduces to

* The work leading toward experimental testing of this latter method is now in progress in the Sylvania Metallurgical Laboratories.

FIG 7—Variation of volume self-diffusion coefficient of silver with temperature as determined from sintering experiments. Logarithm of D_v vs. reciprocal of absolute temperature.

$$\frac{dx}{dt} = \frac{8a^3\sigma\delta^4}{kTx^6} D_s$$

which after integration gives Eq 9. The effect of surface diffusion upon sintering should be noticeable at low temperatures when D_s and x are very small, especially for small particles which have larger surface atom to volume atom ratios, and will sinter by the mechanism of surface diffusion to the longer interface radii x than the large particles. This reasoning seems to be fully substantiated by experiments as seen in Fig 6, where deviations are the larger the smaller are the particles and the lower is the sintering temperature up to about 600°C for the particles

of 10 μ diam or less, the volume diffusion contribution can be neglected and the problem can be treated as surface diffusion only.

In order to prove that the above discussed deviations are really due to surface diffusion, the fine (about 10 μ in diam) copper powder was sintered to the copper block at 600°C for 0.5, 1, and 3 hr. The logarithm of the ratios of the radius of the interface x to the radius of the particle was plotted against $\log t$ (Fig 8) and a straight line was obtained. The inverse slope of this curve $n = 6.5$ is sufficiently close to the theoretical value 7 to indicate that the sintering mechanism in this case is predominantly surface diffusion.

Finally the experimental values of x measured at 400, 500 and 600°C allow us to estimate the surface diffusion coefficients of copper at these temperatures, from Eq 9. The calculated values of D_s are listed in Table 5 along with the values x and a . The semi-logarithmic plot of D_s vs. $\frac{1000}{T}$ is given in Fig 9. The results obtained from two sizes of particles (20 and 8 μ diam) are in excellent agreement with each other. The energy of activation of surface diffusion as determined from the slope of the straight line represented in Fig 9 is $Q_s = 56,000$ cal per mol, the same as for volume diffusion evaluated before. The frequency factor $D_s^0 = 10^7 \frac{\text{cm}^2}{\text{sec}}$ is 10^6 higher than that for volume diffusion which means that although the same energy is required to change the position of an atom on the surface as inside the crystal lattice, the number of atoms possessing this activation energy is much larger on the surface than inside the crystal.

As nobody has ever before measured the coefficient of surface self-diffusion, data obtained in this work cannot be checked but the order of magnitude appears to be reasonable. The fact that energies of activation of volume and surface diffusions are nearly equal may very well be explained by Schottky's¹² mechanism of diffusion. According to him all vacancies are generated on the surface, consequently the energy of the formation of vacancy should be the same in both cases. The only difference should be expected in energies required to move an atom to the adjacent vacancy which in the case of surface migration should be lower than in the case of volume diffusion. It is believed that the greatest part of heat of diffusion is the energy required to make a vacancy on the surface. If this is true the differences in the remaining part of the energy of activation could be small enough to bar detection.

It has therefore been proven that at least for metals of low vapor pressure the rate of interface formation among sintered particles is a process controlled in the early stage by surface diffusion and in the later stage by volume diffusion. No other mechanism such as viscous flow which has been considered by Frenkel¹ and Shaler and Wulff² seems to be involved. The process of sintering by volume diffusion excludes the possibility of an atom exchange mechanism of diffusion^{4,13,14} because in such a case no gradient

FIG 8—Logarithm of the ratio of the interface radius x to the radius a of the small copper particles (about 4μ) sintered at 600°C , plotted against the logarithm of sintering period t .

driving the atoms towards the interface, is possible. It seems to appear then that diffusion in solids proceeds through the mechanism of imperfections in the lattice such as vacancies or interstitial atoms.

Conclusions

1. It has been proven experimentally that the mechanism of sintering of two metallic particles or of a metallic particle and a flat metallic block at atmospheric pressure is predominantly that of volume diffusion for large particles and higher temperatures.

2. It is possible to measure the coefficient of self-diffusion without radioactive tracers, measuring only the rate of growth of the interface between round particles and a metallic block. The method has been checked successfully in the case of copper and silver.

3. Strong experimental evidence has been presented that at the beginning of sintering surface diffusion is operative.

4. The surface diffusion coefficient of copper has been determined.

Acknowledgment

The author wishes to express his gratitude to Mr. W. E. Kingston, Manager of Sylvania Metallurgical Laboratories, for his support of this project. Greatest indebtedness and gratitude are due to Dr. I. Zavarine of Sylvania Electric Products Inc. for his priceless suggestions and help in the experi-

mental part of this work, and to Dr. C. Herring of Bell Telephone Research Laboratories for frequent helpful discussions of the theoretical part of this

paper. The author wants to thank Mrs. L. Roth of Sylvania Electric Products Inc. for her skillful metallographic work.

A Simple Constant Stress Creep Test

J. C. FISHER* and R. P. CARREKER*

CREEP tests are normally constant load tests. Such tests approximate some types of service conditions and therefore are justified from the engineering point of view. Coupled with this consideration is the advantage of simplicity inherent in constant load tests, as contrasted with the comparatively complex requirements of a constant stress test. It is not surprising that the vast majority of creep tests reported are of the constant load type.

Despite the enormous amount of accumulated creep test data, plastic flow is by no means completely understood. The widespread use of constant load tests is at least partly responsible for this lack of understanding. Any attempt to analyze deformation must involve the more fundamental quantity stress, rather than load. It is possible to predict constant load behavior from known constant stress data, but the reverse is much more difficult.

When a metal specimen elongates, as in a creep test, the cross section decreases, maintaining constant volume. Thus

$$\frac{A}{A_0} = \frac{l_0}{l} \quad [1]$$

For a constant stress test the force on the specimen must be decreased as the cross section decreases, that is, this force must be inversely proportional to the elongation of the specimen. Andrade has described three methods of obtaining the constant stress condition,¹⁻³ each of which is relatively complex. The most recent proposal,³ suggests a major simplification which maintains the simplicity of the constant load test while approximating quite closely the desirable condition of constant stress. Andrade's device is admittedly more accurate but the method described below has definite advantages.

Consider a specimen in the form of a

FIG 1—Variation of stress with initial angle.

“V” supported at its ends. If a weight be applied at the vertex of the angle, the stress in each leg of the “V” is

$$S = \frac{w}{z} \cdot \sec \frac{\alpha}{z} \cdot \frac{1}{A} \quad [2]$$

If this stress causes an elongation Δl in each leg of the “V,” the angle decreases from α_0 to a smaller angle α_1 . The quantity $\sec \frac{\alpha}{z}$ thus decreases with specimen elongation while the quantity $1/A$ increases. By selecting proper initial conditions it should be possible to hold S/S_0 very nearly constant at unity.

The proper initial conditions are realized when α_0 is made equal to approximately 90°. Fig 1 compares the ratios of S/S_0 for $\alpha_0 = 85, 90, 95, 100^\circ$, with $\alpha_0 = 0$, that is, a straight speci-

men, for true strains up to $\epsilon = 0.10$. It may prove convenient to measure X , the movement of the vertex, rather than the true elongation Δl . Contour lines of X/l_0 are also plotted in Fig 1.

The method for obtaining constant stress described above is especially suited to the testing of small wires, but may easily be extended to rods of any diameter through the use of a suitable grip which serves as the vertex joining two identical rods forming the legs of the “V.”

Homogeneous Yielding of Carburized and Nitrided Single Iron Crystals

A. N. HOLDEN* and J. H. HOLLOMON,* Junior Member AIME

Introduction

INHOMOGENEOUS yielding during the early stages of plastic flow has been observed in many metals and has long been a subject of controversy.

Low carbon steel, when strained at room temperature, exhibits a distinct yield point at which the metal ceases to behave elastically and begins to flow plastically without further increase in stress,[†] often with an actual decrease in stress from that existing at the yield point. One manifestation of this behavior is the familiar Lüders lines. The extent of the yield point elongation (the plastic strain which results without raising the stress above that at the initial yield point) may be several percent.

Several explanations of this type of yielding in steels have appeared in the literature:^{1-3†}

1. The segregation of carbides or other constituents at the grain boundaries of ferrite forms cell-like blocks which break down at a higher stress than that at which the ferrite alone will flow.

2. The precipitation of various constituents within the ferrite itself in some way blocks initial flow until a higher stress is reached, after which a great deal of flow occurs without further increase in stress.

3. The restraining influence of neighboring, less favorably oriented grains in a polycrystal results in a storing up of energy, which on yielding is sufficient to cause the continued propagation of slip bands on the multiplicity of slip systems available in adjacent iron

[†] Other types of inhomogeneous or discontinuous yielding have been observed in aluminum and other aging alloys as well as in some fairly pure metals. The terms inhomogeneous, heterogeneous, or discontinuous yielding used in this paper refer to the particular initial yielding of steel tested at room temperature.

[†] An excellent bibliography of the subject appears in Ref. 2.

FIG 1—Shape of iron specimens.

crystals without increase in stress.

4. Local segregation of carbon atoms increases the stress required for the initial propagation of dislocations. The stress required for further deformation is lower.³ Such an explanation would require the presence of upper and lower yield points in single crystals.

Low and Gensamer² have shown that heterogeneous yielding can be eliminated by removal of carbon and nitrogen from polycrystalline steels by wet-hydrogen treatment. They also demonstrated that the re-introduction of minute amounts of carbon or nitrogen caused a return of the yield point.

Observations of the initial flow of single crystals containing small amounts of carbon and nitrogen should provide a clue to the explanation of

inhomogeneous yielding. Previous tests of iron crystals⁴⁻⁶ can not be considered conclusive because it is uncertain whether the carbon and nitrogen were satisfactorily removed by the decarburization technique employed.

The purpose of the experiments described herein was to determine whether single iron crystals containing either carbon or nitrogen would exhibit inhomogeneous yielding.

Experimental Procedures

THE PREPARATION OF SINGLE CRYSTALS

All crystals were formed in the following way. Aluminum killed sheet material 80 mils thick was machined into specimens of the outer contour shown in Fig 1. These mildly tapered specimens were decarburized at 730°C for 16 hr in hydrogen that had been bubbled rapidly through water maintained at 70°. The resultant grain size after decarburizing was approximately ASTM 5. Several stress-strain curves were made of the decarburized mate-

rial, two of which are shown in Fig 5. The material as-wet-hydrogen treated yielded homogeneously. Nothing is known of the production history of the sheet prior to the decarburization treatment.

The material used for these specimens was analyzed before and after decarburization (carbon was determined by low pressure combustion and nitrogen by a Kjeldahl determination). The analyses were:

| As-received | Pct | Wet-Hydrogen Treated | Pct |
|------------------|---------|----------------------|---------|
| C | 0.090 | C | 0.004 |
| N | 0.0045 | N | 0.003 |
| *Al | 0.09 | *Al | 0.09 |

| * Total aluminum | | | |
| † Spectrographic | | | |

After the wet-hydrogen treatment, the tapered specimens were strained until the change in area of the reduced section as measured with a micrometer was 2.7 to 3 pct. Subsequent annealing in pure dry hydrogen at 885°C for 72 hr converted the tapered specimens into large crystals.* Several crystals were as wide as the specimens and 4 in. in length. However, the surface of the specimens contained fine grains which had to be removed by grinding before the large crystals could be revealed by etching. It was found necessary to grind 10 mils off each flat surface with a special wheel. A photograph of a typical specimen after grinding and etching appears in Fig 2, showing the size of recrystallized grains resulting from the treatment described.

The important features of the strain-anneal method used in these experiments are the following: First, the specimens were so shaped that recrystallization was limited to a small volume of critically strained material in the narrowest region. Second, a grain formed in the critically strained region readily grew to the lesser strained regions and larger grains resulted. The lesser strained regions were not deformed sufficiently to recrystallize. Third, the specimens were placed in a hot furnace for the annealing treatments.

Tapered specimens have been employed previously,⁷⁻¹⁰ but tapers used have been more extreme than that used in these experiments.

After forming the large grains, crystal tensile specimens were cut out with a jeweler's saw. All of the tapered specimens did not yield large enough grains from which to cut single crystal

* Similar attempts have been made to obtain large single crystals of a "rimming" steel but as yet none has been successful.

FIG 2—Typical crystal size after strain annealing.

tensile specimens. Data are included for all crystals tested. The single crystal specimens had reduced sections of from 3/4 in. to 2 in. in length and from 3/16 in. to 5/16 in. in width.

HEAT-TREATING AND TESTING OF IRON CRYSTALS

The single crystal tensile specimens were annealed in wet-hydrogen at 850°C for 16 hr. All specimens remained single crystals and it was assumed that all machining strains and any remaining carbon were removed during this treatment. Low and Gensamer² have found the carbon to be less than 0.003 pct after wet-hydrogen treatments. Some of the crystals were carburized by the method used by Low and Gensamer. They were annealed at 675°C

for 4 hr in a mixture of butane and hydrogen. Just enough butane was bled into the furnace to color faintly the flame at the furnace door. Several polycrystals were carburized along with the single crystals to make certain that the process was effective. All of these carburized specimens were then homogenized for 5 hr at 650°C in a nitrogen atmosphere obtained by passing tank nitrogen over copper chips at 500°C and activated alumina. After this treatment, the crystals contained 0.005 pct N₂ and 0.019 pct C.

Nitriding of some of the crystals was carried out by treatments of 4 hr at 525°C in an ammonia atmosphere. The hard nitrided case was ground off to a depth where no nitrides were observable metallographically. The crystals were then stress relieved and homogenized for 5 hr at 650°C in a nitrogen atmosphere. Several polycrystalline specimens were nitrided along with the single crystals to make certain the nitriding was adequate. After treatment, the crystals contained 0.004 pct C, and 0.073 pct N₂. This nitrogen certainly exceeds the limit of solubility and probably the crystals contained a precipitated second phase even though it was not observed metallographically.

All the crystals thus far described were tested in a hydraulic tensile machine with Templin sheet grips mounted on spherical seats. Reasonable care was used in alignment. Strain was measured with a single resistance type strain gauge with a sensitivity of 2 × 10⁻⁶. The rate of testing was the

Table 1 . . . Heat-treating and Testing of Iron Crystals

same for all crystals and was such as to give 1 pct strain in 45 min. The methods of heat treating and testing are summarized in Table 1 for crystals thus far described.

It later became evident that more accurate methods of evaluating the effect of carbon and nitrogen on the strength of single crystals would be valuable. Therefore, several experiments were performed on pairs of single crystal tensile specimens cut from the same crystal.

An alternative nitriding procedure to that previously employed was used to nitride the crystal pairs. It consisted of passing hydrogen through a catalytic deoxidizer, activated alumina drier, activated charcoal tube, liquid nitrogen trap, ammonia absorber and into the nitriding furnace at 500°C. The ammonia absorber was kept at -78°C to avoid the formation of any hard nitride case which would have to be removed.

In these experiments the carburization of each of the crystals of the pairs was the same as that employed previously.

One nitrided and one carburized crystal together with their identically oriented wet-hydrogen treated counterparts were annealed in vacuum. It was intended that the temperature of the vacuum anneal would not exceed 750°C but inadvertently it exceeded 910°C. These specimens did not remain single crystals, but became very coarsely polycrystalline.

Orientations were determined for all pairs of crystals except the specimens which became polycrystalline. These orientations are shown in Fig 3.

The testing of crystal pairs was done in a hydraulic machine. Eight of these crystals were pulled with long flexible rods so designed that only axial loads were transmitted (see Fig 4), while the others were tested in Templin grips as previously described.

The eccentricity of the strain in the eight accurately aligned specimens was measured by the following means. Two rigid glass fibers about 6 in. in length were cemented to one side of each specimen perpendicular to the tensile axis and about 3/4 to 1 in. apart. The distance between the ends of the fibers was measured with an accurate micrometer-type cathetometer sensitive to 0.001 mm. The 6-in. lever of the fibers gave a multiplication of the eccentricity of about 64. The relation between the change in readings of the cathetometer and eccentricity can be found provided the strain at the center

FIG 3—Orientation of crystal pairs (cube poles determined with optical goniometer).

line of the specimen is measured.* The average center line strain was measured with two resistance strain gauges cemented to the opposite flats of the specimen.

The edge strain was within 4 pct of the center line strain without any adjustment of the fixtures other than that automatically applied by the flexible tension members.

The heat treating and testing methods for the crystal pairs is summarized in Table 2.

$$* M = \text{eccentricity} = \frac{e - e'}{e} = \left(\frac{w/2}{l} \right) (e - \Delta)$$

e' = strain at edge of specimen
 e = strain at center line of specimen
 w = width of specimen
 l = length of glass fibers
 Δ = change in distance between fiber ends upon application of strain e .

Results

All the data are presented in the form of stress-strain curves.

Fig 5 compares the flow of polycrystalline specimens in the wet-hydrogen treated, carburized and nitrided states. These tests indicate that either carbon or nitrogen causes the return of the discontinuous yield in material which showed no discontinuity in its flow curve as wet-hydrogen treated. The nitrided polycrystals in Fig 5 contained considerable nitrogen (about 0.07 pct) which accounts for their high yield strength. The carburizing treatment on the other hand was quite mild, and the carburized polycrystals showed less increase in yield strength over the wet-hydrogen treated specimens.

FIG 4—Flexible tensile member for axial loading of iron crystals.

Fig 6, 7, and 8 show the flow curves for nine iron crystals. The crystals whose tensile properties are those of Fig 6 were thoroughly treated in wet-hydrogen. The crystals of Fig 7 were carburized and those of Fig 8 were nitrided. None of these crystals yielded inhomogeneously. The high strength of the nitrided crystals is due to the considerable amount of nitrogen these contained.

Fig 9 and 10 show the effect of the described carburizing treatment on the flow of single iron crystals. In these two figures the flow of carburized crystals is compared with that of decarburized crystals of the same orientation. Fig 9 was obtained by testing four crystals cut from the same grain, two of which were carburized and two of which were decarburized. A scattering of the data for two identical crystals is thus obtained as well as the difference in flow strengths of the two materials. Fig 10 is the result of a test of two different pairs of crystals, one of each pair being carburized while the other was decarburized.

While the tests in Fig 9 and 10 were made in Templin grips with only moderate care in alignment, the results are significant. All crystals yielded homogeneously, and allowing for the scatter of the data, the carburized crystals were 5 to 10 pct stronger up to 0.6 to 0.7 pct strain.

Fig 11 shows the yielding of crystals 5-1 and 5-2 of identical orientation. Crystal 5-1 was nitrided under conditions which did not form a hard case. Crystal 5-2 was completely decarburized in wet hydrogen. The nitrided crystal was slightly higher in flow strength than the decarburized crystal. Both crystals yielded homogeneously.

Table 2 . . . Heat-treating and Testing Procedure for Crystal Pairs

| Spec. No. | Heat Treatment | Testing |
|-----------|--|-------------------------------------|
| 1-1 | Carburized | Templin and ball seat |

FIG 9—Yielding of four identically oriented iron crystals. 1-1 and 1-2 were carburized. 1-3 and 1-4 were decarburized. Tested with 2 averaging gauges in Templin grips.

FIG 10—Yielding of iron crystal pairs showing effect of carbon on flow strength. Tested with 2 averaging gauges in Templin grips. Orientation of 4-1 and 4-2 is the same and orientation of 3-1 and 3-2 is the same.

FIG 11—Yielding of identically oriented crystals showing effect of small amounts of nitrogen. Tested with less than 4 pct eccentricity.

FIG 12—Yielding of identically oriented crystals showing effect of small amounts of carbon. Tested with less than 4 pct eccentricity.

slight upward concavity during initial yielding. The flow curve of the nitrided polycrystal contains no upward concavity, but it does flow at a higher stress initially and then drops to approximately the same flow stress as the decarburized polycrystal as flow progresses. Because of the large grain size it is not expected that the flow of these specimens would be greatly different from single crystals.

The original purpose of vacuum annealing was to ascertain whether the hydrogen presumably occluded in the

specimens eliminated the inhomogeneous yielding. Since the vacuum annealed specimens can be considered essentially hydrogen free, the effect of the hydrogen occluded in the specimens is considered to be negligible.

In general, the data on crystal pairs show that where carbon or nitrogen has increased the flow strength, the higher strength curve remains approximately parallel to the decarburized curve, indicating that the rate of strain hardening was not affected.

The results from the tensile tests in

which the specimens were more accurately aligned fail to indicate inhomogeneous yielding in single crystals of iron.

Conclusions

1. Carbon or nitrogen causes discontinuous yielding in iron polycrystals in substantiation of the findings of Low and Gensamer.

2. Carbon or nitrogen do not appear to cause discontinuous yielding in iron

FIG 13—Yielding of extremely coarse polycrystals of iron. Tested with less than 4 pct eccentricity.

FIG 14—Yielding of extremely coarse polycrystals of iron. Tested with less than 4 pct eccentricity.

single crystals made from aluminum-killed steels. Both elements in small amounts cause an increase in the flow strengths of single crystals, but do not affect the rate of strain hardening.

The Surface Tension of Solid Copper

H. UDIN,* A. J. SHALER,* Member, and JOHN WULFF* Member AIME

Introduction

IN the study of the sintering of metal powders, we have come to the conclusion in this laboratory that further progress requires a more basic understanding of the operating mechanisms. This is emphasized in detail by Shaler.¹ He has shown that a knowledge of the exact value of the surface tension is imperative for a solution of the kinetics of sintering. This force plays a principal role in causing the density of compacts to increase.² Furthermore, a knowledge of the surface tension of solids is also applicable to other aspects of physical metallurgy. C. S. Smith³ points out the relation between surface and interfacial tension and their function in determining the microstructure and resulting properties of polycrystalline and polyphase alloys.

This paper describes one group of results of an experimental program designed for the study of the surface tension in solid metals. As a by-product of this work, considerable information has been obtained on the rate and nature of the flow of a metal at temperatures approaching the melting point and under extremely low stresses, a field of mechanical behavior heretofore scarcely touched by metallurgists. The importance of this additional information to students of powder metalurgy need not be stressed.

Theoretical Considerations

Interfacial tension arises from the condition that an excess of energy exists at the interface between two phases. Gibbs⁴ proves that this energy is a partial function of the interfacial area; thus:

$$\partial F / \partial s = \gamma$$

where $\partial F / \partial s$ is the rate of change of free energy of the system with changing

surface area, at constant temperature, pressure and composition, and γ is the interfacial tension, or interfacial free energy per unit area.

If one of the phases is the pure liquid or solid, and the other the vapor of the substance, γ may properly be termed "surface tension," and is a characteristic of the solid or liquid.

The attempt of a body to lower its free energy by decreasing its surface gives rise to a force in the surface which is numerically equal in terms of unit length to the free energy per unit area of the surface. Thus γ may be expressed either in erg-cm⁻² or in dyne-cm⁻¹. Similarly, surface tension may be determined either by a thermodynamic measurement of the surface energy or by a mechanical measurement of the surface force. We have chosen the latter approach.

Tammann and Boehme⁴ determined the surface tension of gold by measuring the amount of shrinkage or extension of thin weighted foil at various temperatures and interpolating to zero strain. The method is of questionable accuracy because of the tendency of foil to form minute tears when heated under tension. Their assumption of $F = 2W\gamma$, where W is the width of the foil, is unsound, as the foil can decrease its surface area by transverse as well as by longitudinal shrinkage. Although their experimentation was meticulous, the paper does not include details of the

sample configuration required for recalculating γ on a correct basis, even if such a calculation were possible.

In the experimental procedure chosen here, a series of small weights of increasing magnitude are suspended from a series of fine copper wires of uniform cross-section. This array is brought to a temperature at which creep is appreciable under extremely small stress. If the weight overbalances the contracting force of surface tension, the wire stretches; otherwise, it shrinks. The magnitude of the strain is determined by the amount of unbalance, so a plot of strain vs. load should cross the zero strain axis at $w = F\gamma$. If balance is visualized as a thermodynamic equilibrium, the critical load is readily calculated. At constant temperature, an infinitesimal change in surface energy should be equal to the work done on or by the weight:

$$ds = wdl \quad [1]$$

$$\text{For a cylinder, } s = 2\pi r^2 + 2\pi rl \quad [2]$$

If the volume remains constant,

$$r = \sqrt{V/\pi l} \quad [3]$$

$$s = 2\sqrt{\pi V/l} + 2V/l \quad [4]$$

$$ds = (\sqrt{\pi V/l} - 2V/l^2) dl \quad [5]$$

Substituting [5] into [1] gives for the equilibrium load,

$$w = \gamma(\sqrt{\pi V/l} - 2V/l^2) \quad [6]$$

and, again expressing V in terms of r and l ,

$$w = \pi r \gamma (l - 2r/l) \quad [7]$$

Here the end-effect term, $2r/l$, is neglected for thin wires in subsequent work.

Eq 7 can be confirmed by means of a stress analysis. If the x -axis is chosen along the wire, then the stress σ_x is

$$\sigma_x = \frac{2\pi r \gamma - w}{\pi r^2} \quad [8]$$

A cylinder of diameter d is equivalent to a sphere of radius r , insofar as radial surface tension effects are concerned.³ Thus

$$\sigma_y = 2\gamma/d = \gamma/r = \sigma_x \quad [9]$$

For the case of zero strain in the x direction, the strain will also be zero in the y and z directions. Since the wire is under hydrostatic stress, Eq 8 and 9 are

equal. Thus

$$2\pi r\gamma - w = \pi r\gamma \quad [10]$$

$$w = \pi r\gamma \quad [11]$$

The end-correction term was again dropped, this time implicitly in Eq 9, which applies to an infinite cylinder.

With certain assumptions it is possible to calculate the strain rate under conditions of unbalance. If pure viscous flow is assumed, there should be no change in lattice energy, and all the strain energy should appear as heat. If the kinetic energy of the moving weight is neglected, the time rate of heat generation must be equal to the rate of change of potential energy and free energy of the system. The system changes its energy by changing both the position of the weight and the area of the copper surface. Thus, under isothermal conditions,

$$dQ/dt = wdl/dt - \gamma ds/dt \quad [12]$$

where Q is the heat of viscous flow.

Frenkel⁶ shows that for a viscous rod under longitudinal strain, the energy dissipated in flow is given by

$$dQ/dt = (6\eta V/l^2)(dl/dt)^2 \quad [13]$$

where η is the coefficient of viscosity. From Eq 5:

$$ds/dt = (\sqrt{\pi V/l} - 2V/l^2) dl/dt \quad [14]$$

Dropping the end-effect term and combining gives:

$$dl/dt = w l^2 / 6\eta V - (\gamma / 6\eta) \sqrt{\pi / V} (l)^{3/2} \quad [15]$$

The equation can be integrated between $t = 0$ at $l = l_0$ and $t = t$, $l = l$;

$$t = 12\eta / \gamma \left\{ -\Delta r + \frac{w}{\pi \gamma} \right.$$

$$\left. \ln \left[\sqrt{\frac{l_0}{l}} \left(\frac{w \sqrt{l} - \sigma \sqrt{\pi V}}{w \sqrt{l_0} - \sigma \sqrt{\pi V}} \right) \right] \right\} \quad [16]$$

Since $dl/dt = l d\epsilon/dt$, $w = \pi r^2 \sigma$, and $V = \pi r^2 l$, ϵ and σ being strain and stress respectively, Eq 15 and 16 reduce to

$$\frac{d\epsilon}{dt} = \frac{1}{6\eta} (\sigma - \gamma/r) \quad [15a]$$

$$t = \frac{12\eta r_0}{\gamma} \left[\frac{\epsilon}{2} + \frac{\sigma r_0}{\gamma} \ln \frac{\sigma r_0^2 - \gamma r}{\sigma r_0^2 - \gamma r_0} \right] \quad [16a]$$

where $r = \frac{r_0}{\sqrt{\epsilon + 1}}$

So long as cylindrical shape is conserved, Eq 16a is an exact expression, despite the presence therein of ordinary stress and strain. This is so because the equation was obtained merely by making the appropriate substitutions in Eq 16. In the actual experiments the strains measured were small enough so that the differential form, Eq 15a, could be employed throughout. It may be written as:

$$\epsilon = \frac{t}{6\eta} \left(\sigma - \frac{\gamma}{r} \right) \quad [15b]$$

FIG 1—Copper cell with thermocouple well.

Experimental

Two series of experiments were completed, one on five mil and one on three mil copper wire. Eight specimens were used in each test, with copper weights, ranging up to about 60 dynes in the first series and 35 dynes in the second series, welded to the wires. (1 dyne is equivalent to 1.02 mg.) The wires were suspended from the lid of the copper cell, Fig 1.

The ensemble was heated in a nichrome-wound Inconel tube furnace, (Fig 2), which was maintained at a Hg pressure of 3×10^{-5} mm. The cell effectively isolated the specimens, both against contamination from furnace vapors and against loss of wire diameter by evaporation. As the experiments were conducted in a temperature range where the vapor pressure of copper was between 10^{-5} and 5×10^{-4} mm,⁷ a good approximation to the isolated system " $\text{Cu}_s - \text{Cu}_g$ " was attained, at least at the higher temperatures.

The furnace was constructed with three independent windings, tapered in accordance with preliminary heat-loss calculations. At any temperature within its operating limits a 6-in. zone can be held uniform to $\pm 2^\circ\text{C}$. A Tagliabue throttling pyrometer with manual droop control was used as a constant-temperature control device. The shell of the furnace was maintained at a low vacuum with a water-aspirator to protect the highly evacuated tube against collapse.

The marking of reference points on the wire presented a difficult problem. Painting or plating the wires outside a given gauge length was considered but was abandoned as it is evident that anything which adheres to the surface lowers the surface energy. Knotting the wire at two points about 2 cm apart was found to be the simplest expedient. The gauge point is taken as the intersection of the lower loop of the knot with the straight portion of the wire, as viewed from a fixed direction with a measuring microscope. (Fig 3.)

The knotted and weighted wires were mounted and carefully straightened. They were annealed in vacuo for 2 hr at or above test temperature before measuring. A test may last from 24 to 150 hr, depending on the temperature. Initial and final lengths were measured to ± 0.001 cm with a horizontal measuring microscope. Finally, the weights were detached at the lower knot and weighed, and the weight corrected by

adding one-half the weight of the gauged length of wire. Table 1 summarizes the results.

Eq 15b is assumed to hold over the range of strains in these tests, and linear least square solutions are plotted. Two such plots are shown in Fig 4. The scatter of the points is within the accuracy of the strain measurements.

Discussion of Results

SURFACE TENSION

It can be seen from Eq 15b that at zero strain the applied stress equals the stress due to surface tension, that is,

$$\gamma = \sigma_{\gamma} r$$

In Fig 5 the surface tensions determined from this relationship are plotted against temperature. If the anomalous point at 1298°K is ignored, a value of 1370 dynes per cm at the melting point is obtained. The temperature coefficient is $-0.46 \text{ dynes cm}^{-1} \text{ }^{\circ}\text{K}^{-1}$, which is consistent, as is to be expected on theoretical grounds,⁸ with an extrapolation to zero in the neighborhood of the critical temperature.

VISCOSITY

As indicated in the introduction, the purpose of this work was to develop an experimental method for the measurement of the surface tension of solid metals. The results on viscosity are a by-product and though interesting should be considered incomplete.

Viscous flow is defined phenomenologically as a process in which strain

rate is proportional to applied shear stress. Recent theory of condensed systems includes the further criterion that the flow must be atomic as well. Steady-state creep is often termed "quasi-viscous" in that the true strain rate, while not proportional to the applied stress, is constant for a constant true stress. Kauzmann⁸ points out that another mode of flow may exist in metals, which involves the motion of blocks rather than single atoms, but which is otherwise proportional to the applied shear stress, at least at low stresses.

Kauzmann's analysis of viscous flow leads to the expression

$$\eta = \frac{\lambda L k T}{2 q A l D} \quad [17]$$

where L = spacing between flow lamellae, normal to flow direction

λ = relative motion of adjacent lamellae, per unit process of flow

q = stress concentration factor, = 1 if no part of the fluid can support shear

A = area of a unit lamella of flow

l = distance between normal and activated state of the flow unit.

D is the coefficient of self-diffusion of the material, if the mechanisms of self-diffusion and of viscous flow are identical. It is only required that the mechanisms correlate. It is not necessary that every unit involved in diffusion be also involved in viscous flow.

For an atom-wise process of self-diffusion, $\lambda = L = (A)^{1/2} = 2l$. For an

atom-wise process of viscous flow under very slight shear, where the probability of a forward jump of an atom exceeds only slightly that of a reverse jump, the relationship $\lambda = 2l$ remains valid. Thus Eq 17 reduces to:

$$\eta = \frac{kT}{\lambda D} = \frac{kT}{\lambda D_0} e^{\frac{Q_D}{RT}} \quad [17a]$$

where λ is now the interatomic spacing. If the Dushman-Langmuir value for D_0 is inserted, the expression becomes:

$$\eta = \frac{h}{\lambda^3} \frac{RT}{Q} \cdot e^{\frac{Q}{RT}} \quad [18]$$

In our experiments the flow is viscous, at least to the extent that the data in Table 1 can be approximated by straight lines. The viscosity is given by

$$\eta = \frac{t}{6\epsilon} \left(\sigma - \frac{\gamma}{\tau} \right) \quad [15c]$$

In Fig 6, the logarithms of the viscosities derived from Eq 15c are plotted against the reciprocal of absolute temperature. The equation of the straight line as drawn is

$$\eta = 130 e^{\frac{95000}{RT}}$$

The activation energy of 59,000 cal per mol is within the range of values reported for self-diffusion of copper.⁹ The action constant, however, is 10^7 times larger than that predicted by Eq 18. The coincidence of activation energies suggests that the atom or atomic vacancy is the unit of flow, but evidently only a very small fraction of vacancies can participate in the flow.

The divergence in viscosity between the two wire sizes, (see dotted lines, Fig 6) indicates that the surface-to-

FIG 6—The temperature dependence of viscosity of solid copper.

volume ratio of the specimens may be a factor in determining the flow rate. Apparently the viscosity of the surface phase greatly exceeds that of the interior of the copper.

The mathematics of this condition has not yet been formulated, nor are the data as yet extensive enough to warrant such formulation. Nevertheless some speculation may be justified.

Surface energy owes its existence to the presence of unsatisfied atomic bonds at the surface. However, if surface tension is calculated by merely summing the energy of these broken bonds, the result is too high by roughly 10 pct¹⁰ because the unsevered bonds in the surface layers of atoms distort in such a way as to take up some of the excess energy. These high-energy bonds might account for the strengthening of the surface layer, according to Benedicks.¹¹

In fatigue testing, and in tension test-

ing of brittle materials, failure is initiated at the surface, and the strength of the surface skin plays an important role, even in large section sizes. Benedicks and Ruben¹² investigated a quenched (untempered) carbon steel immersed in various media, and found the strength to be dependent on the surface tension of the medium.

Further experiments are planned with the purpose of determining the thickness of this surface layer, estimating the ratio of its strength to that of the interior metal, and calculating the effect such a layer will have on sintering rates.

The Ionic Nature of Metallurgical Slags. Simple Oxide Systems

JOHN CHIPMAN,* Member and LO-CHING CHANG,† Junior Member AIME

Introduction

THE perennial and increasing interest in the chemical behavior of steelmaking slags has led to numerous attempts to formulate the thermodynamic properties of these solutions. The classical view is that of a solution of the component oxides in which certain acidic oxides are more or less completely held in combination with basic or metallic oxides, the nature of the interoxide compounds being derivable from the chemical behavior of the slag or from the mineralogy of a solidified specimen. The known electrical conductivity of slags has pointed to the existence of ions in the solution and a number of attempts have been made to account for the observed facts of slag behavior on the basis of a theory of complete ionization of the solution. It is the purpose of this paper to examine, in the light of ionic theory, a number of recently published series of data on slag-metal and slag-gas equilibria, with the purpose of obtaining a more complete or more satisfactory generalization than has been possible on either of the single bases of simple compound formation or complete ionization.

The attempt to formulate the ionic constitution of a complex solution is fraught with many uncertainties. An ion is not something that can be plucked from the solution and examined in detail, nor can its true formula be determined with certainty by any single experimental method. In attempting to express the composition of a slag by various ionic formulas it can be expected that alternative hypotheses of essentially equal merit will present themselves. In the present state of early development of the ionic theory of slags, it may be necessary to make some rather arbitrary choices of ionic formulas in the absence of suffi-

cient information to yield complete certainty.

Acids and Bases

The classification of slag-forming oxides as acidic or basic apparently dates back into the days of Berzelius. It is difficult to see how the concept could have originated in the early twentieth century when it was fashionable to define an acid or a base as an aqueous solution containing hydrogen or hydroxyl ions. It is, however, entirely consistent with the modern and more general theory of acids and bases. In this theory, as originally formulated by G. N. Lewis,¹ a basic molecule is one that has an electron pair which may enter the valence shell of another atom thus binding the two together by the electron-pair bond. An acid molecule is one which is capable of receiving such an electron pair into the shell of one of its atoms. The acid, the base, and the product of neutralization may be either ions or neutral molecules. The product of such a reaction may itself be a base or an acid if it is further capable of giving or accepting an electron pair. Thus a base is a donor of electrons; an acid, an acceptor. In oxide slags the typical and ever-present base is oxide ion, O^{--} . In behavior and in importance it is analogous to hydroxyl ion, OH^- , which is the typical base of aqueous

solutions. There is nothing in the chemistry of slags which is quite analogous to the acid H_3O^+ in aqueous solutions. This is not surprising in slag systems there is nothing which can be designated as a solvent and no ubiquitous positive ion. The chemistry of slags is in fact more complex than the chemistry of aqueous solutions and the concepts which must be evoked in its study are correspondingly broader.

In seeking a basis for a classification of slag-forming oxides as basic or acidic it must be remembered that these terms are not absolute but relative. A substance which acts as a base toward a second substance may act as an acid toward a third. This is less likely to happen among strong bases or acids than among the weak ones; there are numerous examples of weak acids, which under the influence of a stronger acid behave as weak bases. Such substances are called amphoteric. A classification of the glass-forming oxides has been proposed by Sun and Silverman² and further developed by Sun³ in which the oxides are arranged in order of decreasing acidity or increasing basicity, each substance being potentially capable of acting as an acid toward substances below it in the list and as a base toward those above it. It is based upon the relative strengths of the metal-to-oxygen bond as determined by the energy required to dissociate the oxide into its component atoms.⁴ Data are available for computation of this energy, at least approximately, for the oxides of slags and glasses. In general those oxides from which it is most difficult to remove the positive atom are the strong acids while those in which it is most loosely held are the strong bases. It is in the latter, of course, that formation of oxide ion occurs most readily as, for example, in CaO which in solution ionizes to form the weak acid Ca^{++} and the strong base O^{--} . The order of arrangement found by Sun is shown in the first column of Table I, to which have been added the data for

Another method of comparing basic strength of oxides is through studies of the decomposition of such compounds as carbonates and sulphates. The stronger the basic properties of an oxide, the more strongly does it hold fast to CO_2 or SO_3 and accordingly the lower is the decomposition pressure at a given temperature. Acidic oxides may be compared by their relative ability to displace CO_2 from a given carbonate. The information on relative basic strengths derived from experiments of this sort has been summarized by Flood and Förland² and is quoted in the second and third columns of Table 1. It is to be observed that the three columns are in very good agreement although minor discrepancies are present.

On the basis of the Lewis theory of acids and bases the formula for oxide

being used to represent pairs of electrons, not statically placed as in the formula but possessing points of maximum probability which for chemical purposes are sufficiently well represented by the dots. The process of neutralization of the base O^{--} by an acid

 \end{array}$$

The oxide SiO_2 has a crystal structure consisting of a multiplicity of SiO_4 groups, each silicon being surrounded by four oxygens, arranged tetrahedrally, and each oxygen being shared by two silicons. The surface layers of such a crystal might be depicted as:

$$X: \begin{array}{c} X \\ \vdots \\ \text{Si} \\ \vdots \\ \text{O} \end{array} : \begin{array}{c} \vdots \\ \text{O} \\ \vdots \end{array} + : \begin{array}{c} \vdots \\ \text{O} \\ \vdots \end{array} \rightarrow \begin{array}{c} \vdots \\ \text{Si} \\ \vdots \\ \text{O} \end{array} : \begin{array}{c} \vdots \\ \text{O} \\ \vdots \end{array}$$

metasilicate minerals and which may be depicted by the formula:

Further addition of oxide ion to a silicate melt carries the neutralization a step farther, forming pyrosilicates $[\text{SiO}_{3n+1}]^{(2n+2)-}$. To take the simplest case (and the one which is most probably significant in slags) of a pyrosilicate containing two silicon atoms, its formation is represented by:

$$\begin{array}{ccccccc}
 & \ddot{\text{O}} & & \ddot{\text{O}} & & & 6- \\
 & : & \text{O} : & & : & \text{O} : & \\
 & \ddot{\text{O}} & & \ddot{\text{O}} & & \ddot{\text{O}} & \\
 : & \text{O} : & \text{Si} : & \text{O} : & \text{Si} : & \text{O} : & + : \text{O} : \text{---} = \\
 & \ddot{\text{O}} & & \ddot{\text{O}} & & \ddot{\text{O}} & \\
 & : & \text{O} : & & : & \text{O} : & \\
 & \ddot{\text{O}} & & \ddot{\text{O}} & & &
 \end{array}$$

It is evident in these illustrations that the product of neutralization in one reaction may act as an acid in another. The successive steps and the relative acidity of silicon in the several forms may be represented by the following series adapted from the work of Huggins and Sun⁴:

| | Acid | Decreasing Acidity | | | Basic |
|-----------------------------------|------------------|--------------------------------|--------------------------------|--------------------------------|--------------------------------|
| Ion..... | SiO ₂ | SiO ₃ ²⁻ | SiO ₄ ³⁻ | SiO ₅ ⁴⁻ | SiO ₆ ⁴⁻ |
| Atoms of Si per atom of O..... | 0.50 | 0.40 | 0.333 | 0.286 | 0.250 |
| Energy per tetrahedron K cal..... | 3110 | 3123 | 3131 | 3137 | 3141 |

OTHER ACIDIC OXIDES

Phosphorus likewise has a coordination number of four and forms meta-, pyro- and orthophosphate ions whose formulas in order of neutralization are: P₂O₅, PO₃⁻, P₂O₇⁴⁻, PO₄³⁻. Similarly the other acidic oxides react with oxide ion to produce anions which become progressively less acidic as the oxygen content increases. In general the nature of these ions is less thoroughly understood than in the examples cited above, especially with respect to ionic constitution in liquid slags at steelmaking temperatures. It is sometimes possible to deduce the nature of the ion from its known chemical behavior in the slag. For example, in basic open-hearth slags the acidifying effect of one mole of Al₂O₃ is neutralized by addition of two moles of CaO. The neutralization in slags of this kind is therefore very probably represented by the equation:

Other oxides of similar formula may form ions of quite different type. Thus the strong acid B₂O₃ if completely neutralized gives

BASIC OXIDES

Any oxide which when added to the slag increases its oxide ion activity is a basic oxide. The most strongly basic oxides are those of the alkali and alkaline earth metals. In addition to oxides, the fluorides, chlorides and sulphides should be considered. Their behavior is altogether analogous to that of oxides, the negative ions F⁻, Cl⁻ and S²⁻ acting as bases.

An amphoteric oxide may function either as an acid or a base depending upon the oxide-ion activity of the solution to which it is added. As a typical example, alumina may ionize in accordance with either of the following reactions:

It may thus increase or decrease the oxide ion activity depending upon whether the basicity of the slag to which it is added is small or great.

Ionic Solutions

Fused salts are excellent conductors of electricity and, especially in the case of the halides, have long been regarded as highly ionized. Many fused oxides, including the mixtures which we call slags, are also strong electrolytes⁷ and therefore are in considerable measure dissociated into ions. Herasymenko⁸ proposed that open hearth slags are completely dissociated into positive metallic ions and several kinds of negative ions including many of those mentioned in the foregoing section. He showed excellent agreement between theory and observations in many cases of slag-metal equilibrium with acid slags. The success of the theory with respect to basic slags was less noteworthy. Temkin⁹ defined an ideal ionic solution and applied the concept to steelmaking slags. He defined the ion fraction of a positive or negative ion N_i⁺ or N_i⁻ as the ratio of the amount of this ion to the total of all ions of like sign present in the solution. He treated ionic solutions as being "ideal" in the sense that the activity of each ion is equal to its ion fraction. Samarin, Temkin and Shvarzman¹⁰ showed excellent agreement between theory and observations in the distribution of sulphur but unfortunately not for the case of oxygen distribution between slag and metal. We shall refer to the assumed equality of activity and ion fraction as "Temkin's rule."

Liquid Iron Oxide Slags

From the ionic viewpoint, the behavior of liquid iron oxide indicates

clearly the presence of Fe⁺⁺, O²⁻ and at least one other negative ion containing trivalent iron. That trivalent iron is present as an anion rather than as tripositive ferric ion is shown by the marked increase in ferric iron which attends an increase in slag basicity, other factors remaining constant. Which of a number of possible "ferrite ions" is present in basic slags cannot be decided on the basis of any evidence now available. A series of possible ions formed from ferric ion by successive neutralization with oxide ion is suggested as follows:

Since the composition of the liquid may be expressed in terms of Fe⁺⁺, O²⁻ and any one of the anions suggested, the choice of one of these becomes a matter of convenience. It will be convenient to select the formula which leads to values of activity coefficient nearest to unity, or least variable with composition. A simple calculation from the recent data of Darken and Gurry¹¹ showed that Fe₂O₅⁴⁻ is the most satisfactory of the four ionic formulas suggested, from the standpoint of simplicity of calculation. The occurrence of dicalcium ferrite in solidified basic slags¹² indicates that this choice is not an unreasonable one.

Darken and Gurry¹¹ have established the equilibrium relationship between molten iron oxides and a gas phase containing CO and CO₂. Their data cover a temperature range from 1400 to 1600°C and compositions represented by ratios of oxygen to iron between 1.01 and 1.37. They provide as complete a set of experimental data as could be desired for thermodynamic study of these molten oxides. The data for 1600° are reproduced in Table 2 in which the first three columns are taken directly from Darken and Gurry's Table 6. The figures in the other columns will be discussed later.

In view of what has been said above with regard to the principal ions present in the solution, the principal reaction and its equilibrium constant may be written:

$$K_1 = \frac{p_{\text{CO}}}{p_{\text{CO}_2}} \cdot \frac{a_{\text{Fe}_2\text{O}_5^{4-}}}{(a_{\text{Fe}^{++}})^2 \cdot (a_{\text{O}^{2-}})^4}$$

In this expression the *a*'s represent activities of the ions and it will be well at the outset to state clearly the meaning of this term. Ion activity may be defined like any other activity as

$$a = e^{\frac{\mu - \mu^\circ}{RT}}$$

where μ and μ° are the chemical potentials (free energies) of the ionic component at two concentrations, one of which, μ° , is selected as a standard for reference. The activity has no absolute value since it depends only on the difference in chemical potential; for this reason it is sometimes called the relative activity. Darken and Gurry chose as their standard state a solution in which $N_{\text{O}}/N_{\text{Fe}} = 1.07$ and it was on this basis that the third column of Table 2 was obtained. For our purposes it will be more convenient to adopt $N_{\text{O}}/N_{\text{Fe}} = 1.00$ as the standard state, corresponding to the hypothetical pure liquid FeO. Referred to this standard, the value of $\log a_{\text{FeO}}$ will differ by a constant amount from that of the third column, the new values being given in the fourth. The constant difference of 0.040 was found for each of the experimental temperatures by extrapolation to unit ion fraction of oxide ion. Corresponding values for the activity of FeO are given in the last column.

In the pure liquid FeO the activities of the ions Fe^{++} and O^{--} as well as of the component FeO will be taken as unity. These choices require that

$$a_{\text{FeO}} = a_{\text{Fe}^{++}} \cdot a_{\text{O}^{--}} \quad [2]$$

an equation which we shall use as the definition of the activity of FeO in any slag. It should be noted specifically that nothing has been said about the degree of ionization of FeO. The definition of activity here employed* is equally useful whether the melt is completely or only infinitesimally ionized. The activity coefficient, γ , of an ion will be defined as the ratio of its activity to its ion fraction. For other ions in the solution, such as $\text{Fe}_2\text{O}_5^{4-}$ or Fe^{3+} the reference state will be the infinitely dilute solution in FeO in which the activity is equal to the ion fraction or $\gamma = 1$.

The equilibrium constant of Eq 1 may be obtained from the data of Darken and Gurry.¹¹ For slags in which the ratio of $N_{\text{O}}/N_{\text{Fe}}$ is 1.15 or less and the concentration of Fe^{3+} ion is probably quite small, the calculations are shown in Table 3. The first two columns are the experimental data of Darken and Gurry's Table 6. Columns 3 and 4 are ion fractions computed from column 1 on the assumption that the liquid contains only Fe^{++} , O^{--} and $\text{Fe}_2\text{O}_5^{4-}$. Since the ion fraction of Fe^{++} is unity, the activity of O^{--} is equal to that of FeO by Eq 2. Values of a_{FeO} were shown in Table 2 for 1600° and at

other temperatures may be obtained in the same manner from the experimental data. They are listed in the fifth column as $a_{\text{O}^{--}}$. It is to be noted that these experimental values of $a_{\text{O}^{--}}$ agree closely with $N_{\text{O}^{--}}$ thus making $\gamma_{\text{O}^{--}} = 1$ for these solutions.

The activity of this ion thus conforms to Temkin's rule. Now in binary solutions if one component obeys Raoult's law over a given range of composition it follows that the second component obeys Henry's law in the same range. By analogy then, since there are two negative ions, if one obeys Temkin's rule the activity of the other is proportional to concentration in the same range. It follows that in these solutions $\gamma_{\text{Fe}_2\text{O}_5^{4-}}$ (referred to the infinitely dilute solution) is unity. The values of the equilibrium constant computed from the ion fractions are given in the last column, the constancy being surprisingly good. Since deviations occur at higher ratios of oxygen to iron, the values at the lower concentrations are used to obtain the average values of K_1 .

The deviations in K_1 which occur at ratios of $N_{\text{O}}/N_{\text{Fe}}$ greater than 1.15 could readily be treated by imposing an activity coefficient upon any of the ion

fractions involved, for example $\text{Fe}_2\text{O}_5^{4-}$. We prefer to accomplish the same purpose by the hypothesis that at higher ferric contents the concentration of the ferric ion, Fe^{3+} , becomes significant. It is likely that as the concentration of $\text{Fe}_2\text{O}_5^{4-}$ ion increases and that of O^{--} ion decreases, a significant amount of $\text{Fe}_2\text{O}_5^{4-}$ ion dissociates into Fe^{3+} and O^{--} according to some internal equilibrium which we express by the following equations:

$$K_3 = \frac{(a_{\text{Fe}^{3+}})^2 (a_{\text{O}^{--}})^5}{(a_{\text{Fe}_2\text{O}_5^{4-}})}$$

When Fe^{3+} ion is present in significant amount, it becomes no longer possible to calculate the concentration of each constituent directly from the $N_{\text{O}}/N_{\text{Fe}}$ ratios without knowing the constant K_3 and the corresponding activity coefficients. However, we shall proceed to solve the problem from the Darken and Gurry data as follows:

From Eq 1 and our definition of a_{FeO} , and continuing the assumption of unit activity coefficient for oxide and ferrite ions, we may write:

$$K_1 = \frac{p_{\text{CO}}(1 - N_{\text{O}^{--}})}{p_{\text{CO}_2} \cdot (a_{\text{FeO}})^2 \cdot (N_{\text{O}^{--}})^2} \quad [1a]$$

This expression is solved for each of the data to yield $N_{\text{O}^{--}}$ and $N_{\text{Fe}_2\text{O}_5^{4-}}$ (which

* This follows the standard treatment of ion activities by Lewis and Randall; see Ref. 17, p. 326.

is $1 - N_{\text{O}^{--}}$). The solution is shown in the first five columns of Table 4 of which the first three represent the experimental data. The fourth and fifth columns are obtained by solution of the above equation using values of K_1 from Table 3. The ion fraction of Fe^{++} is found from the stoichiometric requirements (a) that the ratio of the total number of atoms of the two kinds must be that of column one and (b) that the total positive and negative charges must be equal. From these considerations we have:

$$\begin{aligned} (N_{\text{O}^{--}} + 5N_{\text{Fe}_2\text{O}_5^{4-}}) / (2N_{\text{Fe}_2\text{O}_5^{4-}} + n_{\text{Fe}^{++}} + n_{\text{Fe}^{3+}}) &= N_{\text{O}}/N_{\text{Fe}} \quad [a] \\ 2n_{\text{Fe}^{++}} + 3n_{\text{Fe}^{3+}} &= 2N_{\text{O}^{--}} + 4N_{\text{Fe}_2\text{O}_5^{4-}} \quad [b] \end{aligned}$$

Here N represents ion or atom fractions while n is the number of moles of ferrous and ferric ion respectively per mole of total negative ion. Simultaneous solution of Eq a and b leads to the value of $N_{\text{Fe}^{++}}$ shown in column six which in these solutions is equal to $n_{\text{Fe}^{++}}/(n_{\text{Fe}^{++}} + n_{\text{Fe}^{3+}})$.

The activity of ferrous ion in column seven is obtained by Eq 2 from the activity of FeO and the ion fraction of oxide ion which is here assumed equal to its activity. The activity coefficient shown in column eight is remarkably close to unity but the deviations are not negligible.

In order to obtain activity coefficients of Fe^{3+} , we shall assume that the activities of the two positive ions follow the same relationship as that governing the behavior of two components in a binary system. By analogy with the Gibbs-Duhem equation¹⁷ we write:

$$\log \gamma_{\text{Fe}^{3+}} = - \int_0^N \frac{N_{\text{Fe}^{++}}}{N_{\text{Fe}^{3+}}} d \log \gamma_{\text{Fe}^{++}}$$

The integration covers the composition range extending to "pure" FeO and consequently involves a rather gross extrapolation. The uncertainty thus introduced corresponds to a constant factor in the activity and hence does not affect the relative accuracy. The resultant values of the activity coefficient and the activity of Fe^{3+} are given in Table 4. Finally the values of K_3 based upon these data are shown in the last column. The surprisingly good

constancy may be due as much to the method of obtaining $\gamma_{\text{Fe}^{3+}}$ as to any other factor, but it should be noted that these values themselves do not vary greatly and a fairly constant K_3 could have been obtained using ion fractions for activities.

The Distribution of FeO between Molten Iron and Oxide Slags

PURE IRON OXIDE SLAGS

From the ionic viewpoint the distribution of FeO between molten iron and liquid iron oxide may be expressed by the following equation:

$$K_4 = \frac{a_{\text{FeO}}}{\% \text{ O}} = \frac{a_{\text{Fe}^{++}} \cdot a_{\text{O}^{--}}}{\% \text{ O}}$$

The experimental data^{13,14} on the distribution of FeO between molten iron and liquid iron oxide containing small amounts of CaO, MgO and SiO₂ are used to determine the distribution constant K_4 . The most probable ion species in these slags are: Ca^{++} , Mg^{++} , Fe^{++} , O^{--} , SiO_4^{4-} and $\text{Fe}_2\text{O}_5^{4-}$. Since the con-

centration of ions other than Fe^{++} and O^{--} is very low, the activity coefficient of Fe^{++} and O^{--} will be close to unity and as an approximation ion fractions may be used for activities.

A plot of $\log K_4$ vs. $1/T$ is shown in Fig 1. The straight line is represented by the equation

$$\log K_4 = +6000/T - 2.57 \quad [4a]$$

This is essentially equivalent to the equation used by Taylor and Chipman¹⁴ to represent the same series of data. It differs slightly because of the different standard state used here and the different method of correcting for impurities.

When the slag is in equilibrium with molten iron, it contains a small concentration of trivalent iron in the form of ferrite ion as shown by the equation

$$K_5 = \frac{a_{\text{Fe}_2\text{O}_5^{4-}}}{(a_{\text{Fe}^{++}})^3 \cdot (a_{\text{O}^{--}})^5}$$

Values of K_5 are readily obtained from the data of Darken and Gurry. Using their limiting gas and oxide compositions, with a small correction to correspond with liquid iron, and our average values of K_1 , we find at temperatures of 1600, 1500 and 1400°C that $K_5 = 0.0255, 0.0316$ and 0.0395 respectively.

IRON OXIDE SLAGS CONTAINING LIME OR MAGNESIA

When liquid iron oxide slags containing varying amounts of lime or magnesia in solution are at equilibrium with molten iron, the concentration of

FIG 1—Temperature dependence of the ionic distribution constant for oxygen between iron and iron oxide slags. $K_4 = a_{\text{Fe}^{++}} \cdot a_{\text{O}^{--}}/\% \text{ O}$. Circles, Chipman and Fettes;¹³ squares, Taylor and Chipman.¹⁴

FIG 2—Activity coefficient of oxide ion in slags containing the oxides of iron, calcium and magnesium.

oxygen in the metal phase serves as a convenient measure of the activity of FeO in the slag. The concentration of ferrite ion in the slag at equilibrium with molten iron is relatively low but increases with increasing percentages of CaO or MgO. That of Fe³⁺ is entirely negligible.

Activities of Fe⁺⁺, Ca⁺⁺ and Mg⁺⁺ may be assumed equal to their ion fractions. The activity of O⁻⁻ is obtained from that of Fe⁺⁺, the oxygen content of the molten iron in equilibrium with the slag, and the value of K_4 given in Eq 4a. The data of Taylor¹⁴ and of Fетters and Chipman¹⁵ are used in making the calculations, the results of which are shown in Fig 2. Here the value of the activity coefficient of oxide ion is plotted against the sum of the ion fractions of Ca⁺⁺ and Mg⁺⁺. With a few exceptions the values of γ_{O--} fall in the range 0.9 to 1.15 and appear to be almost independent of the ratio of Ca⁺⁺ to Fe⁺⁺, perhaps increasing slightly with decreasing Fe⁺⁺. The method of computation imposes all of the errors of experiment and of assumptions regarding activities upon the value of γ_{O--} . The fact that the result lies within 10 to 15 pct of unity at all compositions indicates the usefulness of Temkin's rule in these solutions. It shows further that FeO and CaO are almost equal with respect to the amount of oxide ion that each contributes to slags of this type. This finding might reasonably be construed as evidence that both oxides are either completely ionized or not at all.

The activity of Fe₂O₅⁴⁻ ion in these slags may be obtained from the slag compositions and values of K_5 given in the preceding section. The accuracy will be improved somewhat by combin-

ing K_5 with K_4 to obtain the following:

$$K_6 = \frac{a_{Fe_2O_5^{4-}}}{a_{Fe^{++}} \cdot (a_{O--})^3 [\% O]^2} \quad [6]$$

Values of K_6 are given by the following equation which is based upon data previously cited for the other K 's:

$$\log K_6 = +15000/T - 8.32 \quad [6a]$$

Values of the activity coefficient of Fe₂O₅⁴⁻ ion found from these equations and data on lime-iron oxide slags are presented in Fig 3. Here is an entirely different behavior by an activity coefficient than we have found for that of any other ion, the variation being about 100-fold within the observable concentration range. It is true that the method of calculation has piled all the errors of data and assumptions onto this coefficient; but the same data gave activity coefficients for oxide ion approximating unity. Moreover the low coefficient for Fe₂O₅⁴⁻ ion is not related to a high concentration of this ion but is dependent upon a high concentration of the cations Ca⁺⁺ and Mg⁺⁺. It is evident that these two ions exert a very different effect upon Fe₂O₅⁴⁻ than does Fe⁺⁺, the effect being of the nature of an attraction between positive and negative ions. What this means in terms of the structure of the melt cannot be learned from thermodynamics alone. It may be regarded as evidence of a tendency to form complex ions or neutral compounds, or of a more pronounced close-range ordering of positive and negative ions. Flood and Förland⁵ have pointed out other instances in which the stability of similar anions is markedly affected by the nature of the cation. Kheinman¹⁶ called attention to the striking differences between melts of the compositions 2FeO · SiO₂ and 2CaO · SiO₂. The

former is an excellent conductor of electricity and the conductivity is progressively diminished as the latter is added. He regards this as evidence of a change in the coordination numbers of the ions, the Ca⁺⁺ ion being prevented from taking part in the transfer of electricity by a coating of silicate ions. The result is equivalent to the formation of "nondissociated" Ca₂SiO₄. This seems quite analogous to the case of the ferrites.

We now return to the question of what constitutes a basic oxide in slag. How can we, on the basis of ionic theory, account for the differences in behavior between the common basic oxides? That these differences are not due to different degrees of ionization of the oxides themselves has been demonstrated in the case of CaO-FeO slags where the oxide-ion activity is essentially independent of the cation. The evidence thus far presented indicates that differences in the basic strength of oxides becomes apparent only in the presence of anions other than O⁻⁻. And it is the ability of the cation to bind these larger anions into inactive complexes which determines the behavior of the oxide as a base. We shall not attempt a detailed discussion of the nature of these inactive complexes. They may be thought of as neutral ion-groups behaving as molecules or as regions of marked close-range order, or as parts of a network of anions in which the cations of the more strongly basic oxide become more firmly entangled. In representing them by chemical formulas we must for the present disclaim any implication as to structure.

With this understanding we may say that the stronger basic properties of CaO as compared to FeO are due

FIG 3—Activity coefficient of ferrite ion in slags containing the oxides of iron, calcium and magnesium.

to the nearer approach to completion of such reactions as: $2\text{Ca}^{++} + \text{Fe}_2\text{O}_5^{4-} = \text{Ca}_2\text{Fe}_2\text{O}_5$ than in the corresponding reaction of Fe^{++} . There is no conflict between this concept and the statement that a basic oxide is one which increases the oxide-ion activity of the slag. Addition of either CaO or FeO to a slag increases the oxide-ion concentration about equally. But the addition of CaO , by inactivating larger ions such as ferrite, increases the effective fraction of O^{--} and thereby causes a further increase in the oxide-ion activity. Kheinman¹⁶ has shown that this concept is capable of quantitative application to silicate slags and leads to satisfactory results for oxygen and sulphur distribution in slags containing up to 30 pct silica. It is our intention to discuss such applications in more detail in a later paper.

Summary

This paper is a step toward a thermodynamic treatment of slag-metal and slag-gas reactions based upon the assumption of ionization in the slag. The Lewis theory of acids and bases is applied to slags. Basic slags contain oxide ion O^{--} which is itself a strong base. The activity of oxide ion in the slag determines its basicity and a basic oxide is one which will increase the oxide-ion activity of the slag. The

step-wise neutralization of acid oxides by oxide ion is illustrated.

The theory of complete ionization of open hearth slags is discussed and it is shown that ion activities may be useful even without knowledge of the degree of ionization. Temkin's use of ion fraction as a measure of ion activity is a useful approximation; ionic solutions which are ideal in this respect may be achieved by judicious selection of ion formulas.

The data of Darken and Gurry on equilibrium of gases with liquid iron oxides are consistent with the ion formulas Fe^{++} , O^{--} , $\text{Fe}_2\text{O}_5^{4-}$ and Fe^{3+} , the last being significant only in highly oxidized slags. Thermodynamic relationships among these ions are deduced from the data.

Data on the distribution of iron oxide between metal and simple oxide slags is shown to be consistent with the same ion formulas and thermodynamic constants. In iron oxide slags the ion activity coefficients are unity. Addition of CaO or MgO has little effect on the activity of oxide ion but causes a sharp decrease in activity coefficient of $\text{Fe}_2\text{O}_5^{4-}$ ion.

The differences in basic strength of oxides in slags are ascribed to differences in the abilities of the cations to form inactive complexes with the larger anions such as $\text{Fe}_2\text{O}_5^{4-}$ and SiO_4^{4-} .

This paper is based upon part of a study of the behavior of metallurgical slags sponsored by the American Iron and Steel Institute.

Properties of Chromium Boride and Sintered Chromium Boride*

S. J. SINDEBAND,† Member AIME

Introduction

PRIOR to discussing the metallurgy of sintered chromium borides, it is pertinent to outline some of the reasoning behind this investigation and the purposes underlying the work.

This study was initiated as an approach to the ubiquitous problem of a material for service at high temperatures under oxidizing atmospheres, and it was undertaken with a view to raising the 1500°F (816°C) ceiling to 2000°F (1093°C) or better. For the reason that no small, but rather a major, lifting of the high temperature working limit was being attempted, it was felt appropriate that a completely new approach be taken to this problem.

A summary of the thinking behind this approach was published recently by Schwarzkopf.¹ In briefest terms, it was postulated that the following requirements could be set up for a material which would have high strength at high temperatures.

1. The individual crystals of the material must exhibit high strength interatomic bonds. This automatically leads to consideration of highly refractory materials, since their high energy requirements for melting are related to the strength of their atom-to-atom bonds.

2. On the polycrystalline basis, high boundary strength, superimposed on the above consideration, would also be a necessity. Since this implies control of boundary conditions, the powder metallurgy approach would hold considerable promise.

Such materials actually had been fabricated for a number of years, and the cemented carbide is the best example of these. Here a highly refractory crystal was carefully bonded and resulted in a material of extremely high strength. That this strength was maintained at high temperature is exhibited

by the ability of the cemented carbide tool to hold an edge for extended periods of heavy service.

Nowick and Machlin^{2,3} have analytically approached the problem of creep and stress-rupture properties at high temperature and developed procedures whereby these properties can be approximately predicted from the room temperature physical constants of a material. The most important single constant in the provision of high temperature strength and creep resistance is shown to be the Modulus of Rigidity. On this basis, they proposed that a fertile field for investigation would be that of materials similar to cemented carbides, which have Moduli of Rigidity that are among the highest recorded.

The cemented carbide, however, does not have good corrosion resistance in oxidizing atmospheres and without protection could not be used in gas turbines and similar pieces of equipment. It would be necessary then to attempt the fabrication of an allied material based upon a hard crystal which had good corrosion resistance as well.

It was upon these premises that the subject study was undertaken and at an early stage it was sponsored by the U.S. Navy, Office of Naval Research. Since then, it has been carried on under contract with this agency.

Chromium boride provided a logical starting point for such research, since it was relatively hard, exhibited good

corrosion resistance, and, in addition, was commercially available, since it had found application in hard-surfacing alloys with iron and nickel. That chromium boride did not provide a material that met the ultimate aim of the study results from factors which are subsequently discussed. This, however, does not detract from the basis on which the study was conceived, nor from the value of reporting the results which follow.

Chromium Boride

While work on chromium boride proper dates back to Moissan,⁴ there has been a dearth of literature on borides since 1906. Subsequent to Moissan, principal investigators of chromium boride were Tucker and Moody,⁵ Wedekind and Fetzer,⁶ du Jassoneix,^{7,8,9} and Andrieux.¹⁰

These investigators were generally limited to studies of methods of producing chromium boride and determining its properties. Some study, however, was devoted to the chromium-boron system by du Jassoneix,⁷ who did this chemically and metallographically. This system is not amenable to normal methods of analysis by virtue of the refractory nature of the alloys involved, and the difficulties of measurement and control of temperature conditions in their range. Dilatometric apparatus is nonexistent for operation at these temperatures. Du Jassoneix made use of apparent chemical differences between two phases observed under the microscope and reported the existence of two definite compounds, namely: Cr₃B₂ and CrB. These two compounds, he reported, had quite similar chemical characteristics, but were sufficiently different to enable him to separate them.

The easiest method for producing chromium boride is apparently the thermite process, first applied by Wede-

San Francisco Meeting, February 1949.

TP 2519 E. Discussion of this paper (2 copies) may be sent to *Transactions* AIME before May 15, 1949. Manuscript received October 18, 1948; revision received November 26, 1948.

* This paper was also presented, in part, at The International Powder Metallurgy Congress, 1948, Graz, Austria.

kind and Fetzer.⁶ The commercial product, manufactured in the United States, is also made by thermite processes,¹¹ involving a simultaneous reduction of boric anhydride and chromium oxide Cr_2O_3 . A purer product is obtainable by the electrolysis of fused borate baths described by Andrieux.¹⁰

X ray diffraction studies have been made in the present investigation of chromium borides produced by:

1. Aluminum thermite reduction of B_2O_3 and Cr_2O_3 .
2. Carbon and silicon reduction of B_2O_3 and Cr_2O_3 .
3. Electrolysis of fused borate baths.

Samples having widely different compositions were checked in the boron content range of 12 to 20 pct. This range would include both the compositions Cr_3B_2 and CrB . The X ray diffraction patterns, taken on a Philips Norelco Recorder and using Cu ($K\alpha_1$) radiation, were substantially identical over the entire range. Typical patterns are given in Fig 1, 2, and 3, and the analyses of the samples are given in the next column.

| | Chromium Boride Produced by Aluminum Thermite, Pct | Chromium Boride Produced by Carbon and Silicon Reduction, Pct | Chromium Boride Produced by Electrolysis, Pct |
|----------------|--|---|---|

In Fig 3 it will be noted that a strong peak appears at 26.6° which is found relatively weaker in Fig 2. This line reflects the presence of graphite impurities.

The conclusion has been drawn that a single phase exists over this entire range, and that this is true regardless of method of fabrication. A single compound exists in this range, and its structure is maintained in adjacent nonstoichiometric compositions. This compound has, apparently, a so-called "subtractive" lattice, that is, it can

lose some boron without affecting its crystal structure. This is a consequence of the small size of the boron atom relative to the chromium atom. This has led to the conclusion that there is only one compound of chromium boride, within the compositions indicated, and that it corresponds to the formula CrB .

An investigation is presently being made of the actual crystal structure of the compound CrB . This is being carried out by Mr. A. J. Frueh, Jr., at the Massachusetts Institute of Technology, and while this is not yet complete, the author, through the kindness of Mr. Frueh, is privileged to be able to present some data on this structure. The structure of CrB is orthorhombic, and its unit cell has the following dimensions:

$$\begin{aligned} a &= 2.95 \text{ A.U.} \\ b &= 7.80 \text{ A.U.} \\ c &= 2.93 \text{ A.U.} \end{aligned}$$

This cell contains four molecules of chromium boride, which is in accord with its measured density, as reported

in a subsequent paragraph. The four chromium atoms have the following coordinates:

| x | y | z |
|-----|-------|------|
| 0 | 0.145 | 0.25 |
| 0 | 0.855 | 0.75 |
| 0.5 | 0.645 | 0.25 |
| 0.5 | 0.355 | 0.75 |

The positions of the boron atoms have not yet been determined exactly, but this problem is presently under study and will be published by Mr. Frueh when his investigation is completed.

It is of interest at this point to recall that Hägg¹² in his study of phases of transition elements in binary systems with boron, carbon and nitrogen, drew certain general conclusions regarding the structure of such phases. He predicted that the structure could only be a relatively close-packed one if the ratio of the diameter of the transition element atom to that of the interstitial atom was in excess of 1.7. In the case of chromium boride, this ratio is between 1.6 and 1.4 in consideration of the indefinite knowledge of the diameter of the boron atom. Since the structure of chromium boride determined by Mr. Frueh is not a close-packed one, this compound apparently behaves in accordance with Hägg's rule.

Various investigators have reported that chromium boride is relatively slowly attacked by acids. Their results vary to some degree, but this is believed to be the consequence of varying impurity contents. In this investigation it was noted that hydrochloric, sulphuric, hydrofluoric and perchloric acids attack it only slowly. The only one of these capable of dissolving it completely is perchloric acid. Nitric acid attacks it almost negligibly and when dilute can be considered, effectively, to fail to attack it at all. Fused sodium peroxide dissolves it completely, as do nitrate-carbonate mixtures.

Densities varying from 5.4 to 6.7 g per cc have been reported for chromium boride. None of these investigators reported the conditions, other than temperature, under which the determination was made. Depending upon composition, the densities noted in the present study were in the range 6.15 to 6.20 g per cc at 18°C, taken in ethyl benzene by the standard pycnometric method.

The hardness of chromium boride has previously been reported to be about 8.5 on Moh's scale.¹⁰

FIG 4—Schematic diagram of hot pressing.

PRESSING AND SINTERING

Attempts to cold press compacts of chromium boride and a binder when the boride content exceeded 75 pct were effectively unsuccessful. Compacts could be obtained but the resultant body, after sintering up to 1500°C in H₂, showed densities which were low and the attendant physical properties suffered. This is considered to be a direct result of the high hardness and negligible room temperature plasticity of the chromium boride. At an early stage in the work, cold pressing and sintering were abandoned in favor of hot pressing. When hot pressing was carried out at temperatures sufficiently high to melt the binder employed, highly dense bodies resulted having interesting properties.

The hot pressing method used is illustrated diagrammatically in Fig 4. A high current was passed through the graphite die proper, and the heat so generated plus heating occurring as a consequence of current passing through the work itself made it possible to raise the temperature to 1500°C in approximately 1–2 min. When the temperature was reached at which pressing was to occur, the current was stopped and pressing accomplished by hydraulic means. No provision for atmosphere was made, and the carbonaceous atmosphere within the die and the short times involved made it possible to avoid any indication of oxidation. The pressure was uniformly held at 1 tsi.

The most effective binder employed proved to be nickel, and the writer will limit himself to mixtures of 85 pct chro-

mium boride, 15 pct nickel, for the purpose of showing the effects of certain parameters. A comparison with other binders will be made in a latter part of this paper.

The chromium boride powder used throughout the following experiments was that produced by aluminum thermite reduction, the analysis of which has already been given. The nickel powder was spectrographically analyzed to be 99.6+ pct nickel, with small impurities, as follows:

| | Pct |
|--------------|-------|
| Iron..... | 0.22 |
| Zinc..... | 0.03 |
| Copper..... | 0.065 |
| Lead..... | 0.025 |
| Sulphur..... | 0.021 |

The chromium boride powder was first ball milled to a given particle size in either a stainless steel or tungsten carbide-lined mill. The latter type was employed only where the particle size desired required milling times which resulted in excessive pick-up of material from the stainless steel mill. The ball milling medium was distilled water. The balls, in each case, were of the same material as the liner. The fine powder was then ball milled again, to mix it with the binder. Water again was the medium employed. After drying the powder with alcohol, the powder mix was ready for hot pressing.

The powders were pressed into a flat bar shape 1 in. × 0.375 in. × approximately 0.200 in. thick. This shape specimen lent itself readily to transverse rupture testing where the span was $\frac{3}{16}$ in. and the load was applied at the center of the bar and span by means of a 10 mm Brinell ball. This test was the main evaluation method for room temperature properties.

The effect of particle size and temperature of pressing proved to be interrelated and interesting. For any given particle size, an optimum temperature of pressing was noted.

The optimum pressing temperature was lower with each reduction in particle size, although this effect became almost negligible once the particle size was down to 3 to 5 microns.

Optimum conditions applied when the particle size was reduced to 3 to 5 microns, and the temperature of pressing, as measured optically on the exterior of the graphite die, was 1300°C. It is estimated that this corresponded to 1550°C inside the die. Under these conditions the Modulus of Rupture was found to be circa 120,000 psi, and the hardness averaged 89 on the Rockwell A scale. Fig 5 shows the effect of temperature of pressing, under the condi-

FIG 5—Effect of pressing temperature on Modulus of Rupture. 15 pct nickel binder.

tions indicated above, on the Modulus of Rupture.

Decreasing the particle size further, to a point where it fell between 1 and 2 microns resulted in increased hardness values, that is, 90–91 Rockwell A, but resulted in a decreased Modulus of Rupture optimum. This value fell to 85,000 psi.

Increasing the particle size, or the use of particle size distribution having higher average particle size, resulted in decreasing the Modulus of Rupture as well as the hardness.

The density of a cast 85/15 chromium boride/nickel alloy was measured as 6.17 g per cc and the densities obtained by hot pressing the 3–5 micron powder and 1–2 micron powder, as described above, proved to be circa 5.90 g per cc, so that densities of the order of 96 pct were achieved.

The effect of the use of binders other than nickel is best indicated by the following table, in which the optimum Modulus of Rupture obtained is indicated as well as hardness. The particle size employed was 3–5 microns in all cases, and the composition was 85 pct chromium boride, balance binder.

A typical micrograph of a nickel bound specimen is shown in Fig 6.

HIGH TEMPERATURE TESTING

The following tests have been made to indicate the behavior of this material at high temperatures:

1. Hot hardness (70 pct CrB, 30 pct Ni).
2. Stress rupture.
3. Corrosion in air.

The hot hardness tests were made in an atmosphere of N_2 in a furnace specially designed by E. C. Bishop and M. Cohen.¹³ While the tests were made on a slightly different composition than is presently believed to be an optimum,

FIG 6—Chromium boride/nickel, 85/15. Etchant: 4 pct Picral. X500

Table 1 . . . Optimum Results of Chromium Boride Sintered with Different Binders (85/15)

| Binder | Modulus of Rupture (psi) | Hardness R _A |
|-------------------------|--------------------------|-------------------------|
| Nickel | 123,000 | 87.4 |
| Nickel-copper (70-30) | 120,000 | 86.7 |
| Nickel-chromium (60-40) | 113,000 | 88.1 |
| Cobalt | 80,000 | 90.5 |

the effect of the use of the 85/15 would have merely translated the curve given in Fig 7 upwards about one point on the hardness scale.

Stress-rupture tests on the 85/15 composition were carried out at the Battelle Memorial Institute, and the results of the tests are given graphically in Fig 8. The hot strength, if taken at the 1000 hr point, is of the order of one

FIG 7—Hardness variation with temperature.

FIG 8—Stress vs. rupture time curves for nickel-bonded chromium boride.

quarter that of cast Vitallium. (Vitallium composition: 0.2 C, 28 Cr, 2.5 Ni, 62 Co, 5.5 Mo, 1 Fe.)

Table 2 gives typical results obtained when the 85/15 CrB/Ni material was tested in air for corrosion.

It was in the above corrosion tests that a serious limitation of this particular material was noted. It can be seen that there are indications of a liquid phase forming at about 1900°F (1038°C). This liquid phase is caused by the development of less refractory nickel borides and systems of these. Their formation limits the use of this material to a maximum temperature of about 1750°F (954°C). There can be no question that the formation of these lower melting point constituents also influenced the observed strength at 1500° and 1600°F (816° and 871°C). Their formation, however, indicated that further work needs to be done to fabricate a material on similar principles in which such a phenomenon will be absent. This work is in progress.

Summary

It has been determined that only one chromium boride compound exists in the range 12 pct to 20 pct boron content, instead of two, as had previously been reported.

The composition of the above compound is postulated to be CrB, and its structure is reported to be orthorhombic. The dimensions of the unit cell are given as well as the coordinates of the chromium atom.

Table 2 . . . Air Corrosion Tests on Chromium Boride/Nickel 85/15

| Material and Sample No. | Temperature | | Atmosphere | Time hr | Remarks |
|-------------------------|-------------|------|------------|---------|---|
| | °F | °C | | | |
| 85/15 CrB-Ni | | | | | |
| 1 | 1525 | 830 | air | 48 | No reportable change |
| 2 | 1600 | 871 | air | 48 | No reportable change |
| 3 | 1725 | 940 | air | 48 | Slight green oxide coat |
| 4 | 1850 | 1010 | air | 48 | Slight green oxide coat |
| 5 | 1900 | 1038 | air | 48 | Initial indication of liquid phase at surface. Hardness drop from RA 88.5 to 80. No grain size change |
| 6 | 2050 | 1121 | air | 48 | Dark coating formed; distortion. |

New data regarding the properties of this boride are presented.

Experimental results are given of an investigation of the pressing and sintering of chromium boride with nickel as a binder. A Modulus of Rupture of 120,000 psi is reported for such material when hot pressed.

Data are given regarding the high temperature strength and corrosion resistance of the above material. The hot strength at 1500°F (816°C) is of the order of one quarter that of cast Vitallium. The formation of a liquid phase at about 1900°F (1038°C) is noted, and a limitation of use temperature is set at 1750°F (954°C).

PAUL A. BECK,* Member AIME, JOHN TOWERS, JR.,* and PHILIP R. SPERRY*

DAHL and Pawlek¹ found that electrolytic copper develops extremely coarse grains at 1000°C after about 90 pct reduction by rolling. This coarsening occurs only under conditions of penultimate grain size, deformation, and alloying which lead to the "cube" recrystallization texture.^{1,2,3,5} The peculiar angular shapes and straight grain boundaries of the coarse grains were noted by several investigators.^{1,4,6}

On the other hand, coarsening in Fe-containing aluminum or in Al-Mn alloys⁸ does not depend on a "cube" (or any well developed) recrystallization texture. It is true that increasing deformation by rolling, and, therefore, an increasingly well developed recrystallization texture, are associated with decreasing incubation periods of coarsening.^{6,7,8} Nevertheless, coarsening readily develops in aluminum even after only 30 pct reduction by rolling, where the recrystallization texture is very weak.^{6,8} Also, coarsening was observed by Jeffries⁹ many years ago in sintered thoriated tungsten, which presumably has no preferred orientation. In all these cases coarsening is associated with grain growth inhibition by a dispersed second phase.^{8,9} The annealing temperature has to be sufficiently high to overcome the inhibition at a few locations. But if it is too high, growth starts at many points, and the resulting grain size becomes much smaller.⁹ Normally, the coarse grains are more or less equiaxed, and the boundaries have a typical ragged appearance.^{5,8}

Cook and Macquarie⁴ demonstrated that, in addition to the texture-dependent coarsening previously found at 1000°C,¹ electrolytic tough pitch copper may also coarsen at 800°C after 50 pct reduction by cross rolling. The coarse grains formed under such conditions have rounded shapes and ragged boundaries, like those in aluminum. When the annealing temperature is higher, the tendency for their formation decreases. All these observations suggest that the coarsening at 800°C is associated with inhibition by a second phase. Actually, coarsening at 800°C after 50 pct reduction by cross rolling was observed only in tough pitch copper,⁴ which contains Cu₂O particles.

On the other hand, the texture-dependent 1000°C coarsening occurs in both tough pitch and oxygen-free copper;⁴ it does not appear to depend on the presence of a dispersed second phase. However, the interpretation of the 800°C coarsening in Cu after 50 pct rolling as an inhibition-dependent process, similar to the coarsening in Al-Mn alloys, is somewhat weakened by the fact that this coarsening was reported⁴ to occur only after cross rolling, and not after straight rolling. It was, therefore, decided to re-examine this question.

A 1 in. diam electrolytic tough pitch copper rod, No. 2 hard drawn, was annealed for 20 min at 700°C, rolled to 0.5 in., annealed 10 min at 700°C, and straight rolled to 0.064 in. It was then given a penultimate anneal of 20 min at 500°C and it was cut into four sections, which were given final reductions by straight rolling as follows:

- A 30 pct reduction of area
- B 50 pct reduction of area
- C 70 pct reduction of area
- D 90 pct reduction of area

Specimens cut from the four sections were finally annealed at 800°C in an oxidizing atmosphere. Strip A remained fine grained up to 10 hr, but the specimen annealed 12 hr consisted of only 2 large grains. Strip B had a few scattered large ($\frac{1}{2}$ to $\frac{3}{4}$ mm) grains after 1 min, although the balance of the specimen consisted of fine grains of about 0.02 mm. After 5 min there were several 10 to 15 mm grains present, and after 1 hr strip B was completely coarsened. The coarse grains had the same characteristics (see Fig 1) as those obtained by Cook and Macquarie at 800°C after cross rolling. Strip C had several grains of 0.05 to 1 mm after 1 min, but it was still largely fine grained after 12 hr. After 48 hr it consisted entirely of grains of about 0.5 to 4 mm, with an extraordinarily large number of twin bands. Strip D remained com-

FIG 1—Tough pitch copper after final rolling of 50 pct (strip B) and final anneal of 1 hr at 800°C. The coarse grains have rounded shapes and ragged boundaries. Numerous small twins are entirely surrounded by coarse grains. Magnification 5 X. (Reduced approximately one-half.)

FIG 2—Same copper as in Fig 1, after final rolling of 90 pct (strip D) and final anneal of 25 min at 1000°C. The appearance of this structure is dominated by the characteristically long, straight (twin) boundaries. Magnification 5 X. (Reduced approximately one-half.)

pletely fine grained after 4 hr at 800°C. These results indicate that, in the deformation range of 30 to 70 pct reduction, the incubation period for coarsening as well as the rate of growth and the final size of the coarse grains decreases with increasing deformation. Similar

relations were observed in the "inhibition-dependent coarsening" of Al alloys containing a dispersed phase. However, the behavior of the 90 pct rolled copper strip, which has a cube recrystallization texture, is different. Up to 4 hr it does not coarsen at all at 800°C. It coarsens at 1000°C in 3 to 6 min, in a manner typical of "texture-dependent coarsening" (Fig 2).

It may be concluded that coarsening at 800°C, after 30 to 70 pct reduction by rolling, may develop in straight rolled as well as in cross rolled tough pitch copper. This confirms the view that coarsening in Cu₂O-containing copper after 30 to 70 pct rolling is analogous to the coarsening in alumi-

num containing dispersed particles of a second phase.

Solid Nuclei in Liquid Metals

CYRIL STANLEY SMITH, Member AIME

THE partial persistence of grain size and grain shape on melting and resolidifying crystalline substances, as well as the general effects of pre-solidification and of superheating on nucleation rate, have been attributed to the presence in the liquid of crystalline impurities bearing some structural relation to the principal solid and hence capable of serving as nuclei for its crystallization. That such lattice matching does sometimes occur is well established, but it is surely improbable that a compound possessing both high-temperature stability and the requisite structural similarity should be naturally available in almost every system.

It is now suggested that a mechanism for producing appropriate nuclei exists in the crystallization of all but absolutely pure substances. Impurities can be of many kinds. Some will give rise to compounds that are less soluble in the solid crystal than in the liquid. A crystal forming from a melt or solution containing these will be supersaturated in some degree, and the foreign atoms will commence to segregate during or after solidification. They do not necessarily form pure, unstrained, crystals of the precipitating compound with its normal composition and structure. Generally—at least in the metallurgical examples that have been most studied—the first recognizable nuclei have lattice coherency with the surrounding matrix and have practically the same crystal structure and lattice spacing as the material in which they form, differ-

ing only in composition.

An extremely thin oxide layer formed under appropriate conditions on or in a solid metal will tend to be coherent with the metal lattice, and the first few atom layers of the oxide in contact with the metal will differ in both composition and structure from massive crystalline oxide. It will resemble the metal more closely than the oxide. If it did not subsequently change on melting, such an oxide film would constitute an almost perfect "template" or two-dimensional matrix to hold a few atoms of the primary metal in the exact array needed to form a nucleus for solidification.

Any precipitating material will adopt the correct spacing over a few atom diameters, and with appropriate substitution of other atoms of the correct sizes a precipitate can match the parent lattice over large areas of coherence without excessive strain. In metals, the components of a host of oxides, silicides, borides, nitrides, carbides, sulphides, and other compounds are always present in minute amounts. Some of these will be eliminated because of extreme insolubility in the liquid, while others will remain soluble in the solid; occasionally, however, particles will be formed in the solid by coherent precipitation—not of pure substances, but of whatever assortment of atoms best

satisfies the joint requirements of availability, affinity, and appropriate average atom size. Of these, many will disappear on melting, but a few will persist unmelted as little rafts of complex composition, maintaining in the liquid a surface of the exact geometry needed to nucleate the solid on subsequent cooling. Their number and size distribution will determine the resulting grain size; the dimensions of the largest will determine the degree of undercooling that can occur before solidification commences.

A similar process may operate in the case of phase transformations in solids. The coherent precipitation of supersaturated minor constituents in a low-temperature phase should facilitate the nucleation of this phase on subsequent cooling after transforming into another phase at higher temperatures.

At first sight this hypothesis may seem little different from the older ones. It should therefore be emphasized that it does not depend on chance to provide the right compound to form a nucleus, but postulates that every crystal, containing minute amounts of any of a wide range of impurities, automatically engenders particles having the correct surface structure to serve as nuclei for subsequent solidification. It could operate in any system, metallic, organic, or inorganic. The suggested mechanism is closely analogous to the production of antibodies from antigens in living organisms—indeed, it was a description of the matrix theory of this process that suggested to the writer its crystalline analogue.

The Recovery of Cadmium from Cadmium-copper Precipitate, Electrolytic Zinc Co. of Australasia, Risdon, Tasmania

G. H. ANDERSON*

CADMIUM-COPPER precipitate, a by-product of the purification stage of the zinc plant, is composed mainly of zinc, cadmium and copper in varying amounts depending on the efficiency of precipitation and the cadmium and copper contents of the impure solution treated.

The composition range is approximately: cadmium 10–12 pct, copper 6–8 pct, and zinc 30–35 pct. As received at the cadmium plant, the precipitate is a dark gray to black press cake produced by filter pressing the flocculent cadmium-copper precipitate formed when impure zinc solution is agitated with zinc dust.

The details of the cadmium-copper precipitation are to be found in the paper "Electrolytic Zinc at Risdon, Tasmania," by W. C. Snow. *Transactions AIME*, 121, 501.

The treatment, in addition to recovering cadmium as metal, yields a copper product as a residue for realization and recovers in solution for return to the zinc plant, the excess of zinc dust used during purification.

The recovery of cadmium metal is approximately 200 tons† per year, but, with the amount of copper residue

recovered, varies with the zinc production tonnage, composition of the original concentrates, degree of roasting and other operational factors.

The operations involved in the recovery of the foregoing materials are carried out in a building adjacent to the purification section of the zinc plant and can best be described by dividing the process into the following stages:

1. Oxidation and Grinding of the cadmium-copper precipitate.
2. Leaching and Filtering.
3. Precipitation of cadmium.
4. Oxidation and Grinding of the precipitated cadmium.
5. Leaching oxidized cadmium precipitate and Purification of leach solution.
6. Electrolysis.
7. Melting, Casting and Packing.

A feature of the process is the use of two distinct solution circuits. Spent electrolyte from the zinc plant circuit containing about 10 pct sulphuric acid is used as the primary solvent of the

cadmium and zinc present in the oxidized precipitate. When the cadmium is later separated by precipitation and filtering, the filtrate, originally zinc plant spent electrolyte and now fortified in zinc, is returned to the zinc plant.

The precipitated cadmium, after oxidation, is redissolved in spent electrolyte from cadmium electrolysis which solution is in closed circuit within the cadmium plant except for discards to the zinc plant circuit as mentioned in Section 5 hereinafter. (Fig 1.)

Details of the various operations follow.

1. Oxidation and Grinding of the Cadmium-copper Precipitate

The precipitate having had a preliminary drying by compressed air in Dehne filter presses in the zinc plant is trucked to a storage platform of sufficient length to store 3 to 4 days' production separately.

After 48 hr exposure to atmosphere, oxidation is sufficient to enable all cadmium and zinc but only a portion of the copper to be dissolved in dilute sulphuric acid.

The oxidized precipitate is shovelled into trucks and, after weighing and sampling, is broken in size by means of

San Francisco Meeting, February 1949.

TP 2525 D. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before June 15, 1949. Manuscript received October 1, 1948.

* Assistant Operating Superintendent, Electrolytic Zinc Co. of Australasia Ltd., Hobart, Tasmania.

† Throughout this paper the long ton of 2240 lb and the Imperial gallon are used.

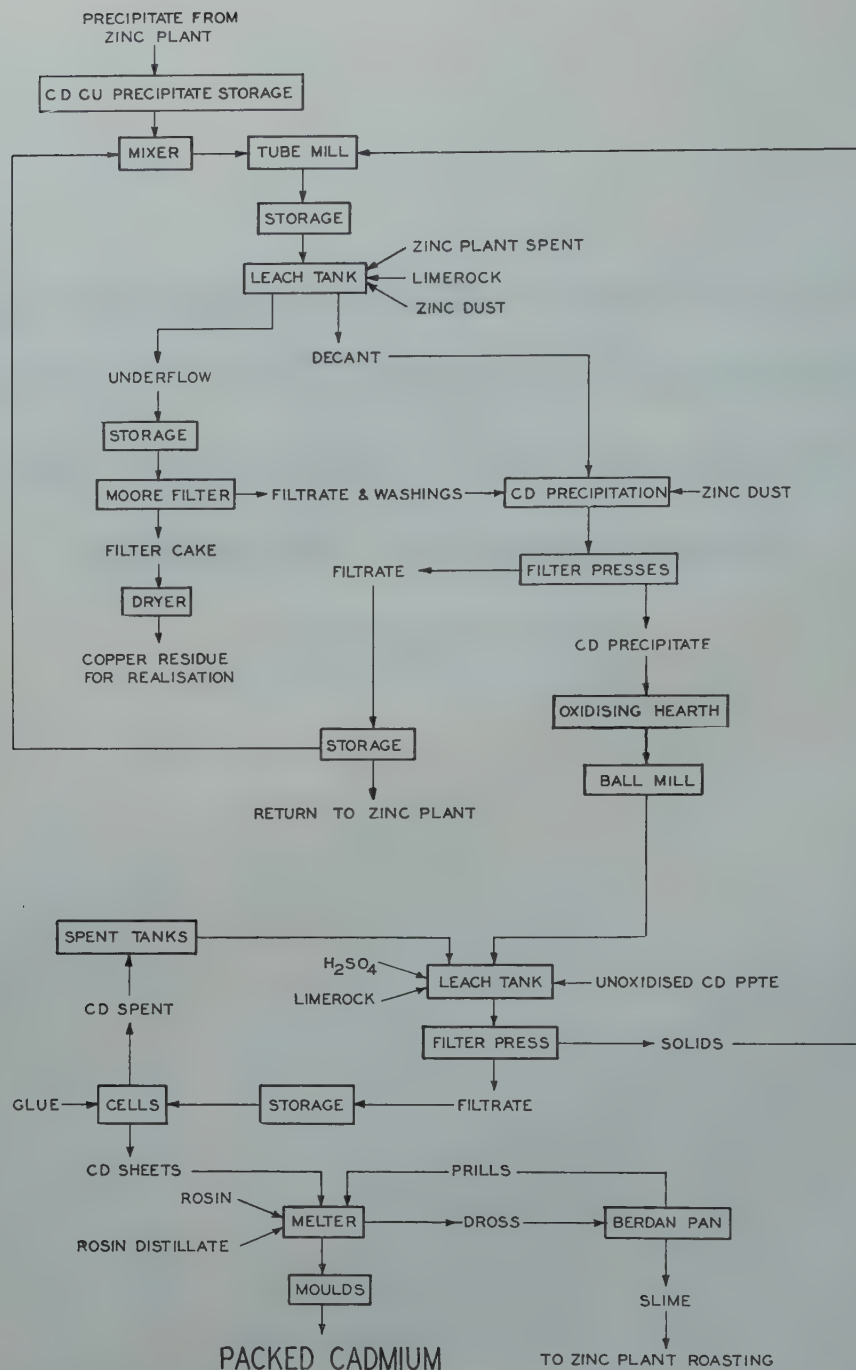

FIG 1—Flowsheet.

right and left handed blades rotating in a shallow mild steel trough.

Return solution (see Stage 3) is added to form a pulp which passes to a tube mill 5 ft long and 3 ft diam having cast steel liners and loaded with flint pebbles.

The use of return solution is restricted to produce a thick pulp which is elevated to a wooden storage tank of 3200 gal capacity and provided with air agitation.

2. Leaching and Filtering

Leaching is carried out in a wooden tank of approximately 14,000 gal capacity, having a conical bottom and provided with both mechanical and air agitation.

Discharge is through a plug cock but, in addition, the tank has a side discharge to which is fitted, inside the

tank, an armored rubber hose for decanting clear solution after settlement of the solids.

The tank is covered and ventilated to atmosphere. Approximately 7000–8000 gal of zinc plant spent electrolyte containing 90–95 g sulphuric acid and 45–50 g zinc per liter are run into the leaching tank and after agitation is started the ground cadmium-copper precipitate is charged until the acidity of the solution falls to 5–6 g sulphuric

acid per liter. Agitation is continued for another 5-6 hr by which time the acidity is reduced to 1-2 g sulphuric acid per liter, then ground limestone is added slowly until a pH 3-4 is reached.

Approximately 30 min. later a sample is taken, tested for copper and the calculated quantity of zinc dust required to remove copper in excess of 0.5 g per liter, is added. (See Appendix 1.)

The zinc dust containing 45-50 pct of minus 250 mesh material, used in this and other stages of the recovery of cadmium, is produced at Risdon by atomizing molten high grade zinc with compressed air at 200 psi pressure.

Control of the copper content of the solution is important, and is considered to have three distinct advantages.

First, its subsequent precipitation with the cadmium in Stage 3 prevents coagulation of the cadmium into metallic balls and facilitates filtering; second, during the cadmium circuit leach (Section 5) arsenic is precipitated or otherwise eliminated, and third, its presence insures a minimum of zinc and cadmium in the copper residue.

If no copper is in the leach solution, sufficient sulphated copper residue is added to give the desired content. Sulphated copper residue is made by mixing copper residue and sulphuric acid and storing in heaps for one or two days.

Approximately 30 min. after the addition of the calculated amount of zinc dust, a further test is taken to determine copper in solution, and if necessary further additions of zinc dust are made.

Agitation is continued for another hour after which solids are allowed to settle for 3 to 4 hr when clear solution is decanted and pumped to the cadmium precipitating tank. (See Section 3.)

The remaining pulp is agitated, air lifted to a wooden storage tank and filtered in a small Moore filter unit.

A cake of about 1/2 in. thickness is formed in 20 min. and washed with water until relatively free of zinc and cadmium.

The filtrate and washings are pumped by wet vacuum pumps to the cadmium precipitation tank containing the decanted leach solution. The filter cake is discharged to a hopper and fed to an oil fired rotary drier 15 ft long and 3 ft 9 in. diam consisting of a mild steel shell lined with 10 ga stainless steel sheet and fitted with suitable angle lifters.

The dried copper residue is bagged

for shipment to a copper refinery at Port Kembla in New South Wales.

3. Precipitation of Cadmium

The precipitation tank is identical in construction to the leach tank previously described except that no decantation hose is fitted and air agitation is not provided.

To the decanted solution, filtrate, and washings derived from the 8000 gal leaching operation described in Section 2 about 600 lb of zinc dust is added after agitation has commenced. Filtered samples of the solution are tested with hydrogen sulphide from time to time and further smaller additions of zinc dust are made until only a trace of cadmium remains.

Approximately 45-60 min. later, if a similar test indicates a satisfactory cadmium content, the pulp is filtered in two 27 in. Dehne filter presses and the filtrate, known as "Return Solution," after by-passing for a few minutes, passes to a storage tank prior to its return to the zinc plant circuit for the recovery of its zinc and cadmium contents.

When the filter presses are full of precipitate, pumping is stopped and a water wash given until a specific gravity of 1.025 shows that the precipitate is almost free of zinc sulphate.

After drying with compressed air the washed precipitate is discharged to hoppers over a drying and oxidizing hearth.

4. Oxidation and Grinding of the Precipitated Cadmium

The oxidizing hearth is of brick construction with a hearth of cast iron plates, approximately 11 by 9 ft mounted so that gases from an oil burner first pass under the hearth and then over the precipitate which, when dropped from the hoppers above, is raked evenly over the hearth to a depth of 4 to 6 in.

As the precipitate oxidizes readily, a maximum gas temperature of 300°C is set at the rising flue from under the hearth to above the charge but rarely is this limit necessary. Hand rabbling proceeds at intervals until the color of the precipitate indicates that oxidation is complete, at which stage the material is discharged by hand rakes to a ventilated hopper from which the precipitate is screw fed to a mild steel ball mill 4 ft long and 2 ft 6 in. diam loaded with 1 1/2 and 3/4 in. steel balls. Cadmium cell feed solution is added to produce a reasonably thick mill discharge which is stored in a wooden tank ready for air lifting to the leach tank (Stage 5) when required.

For ventilation purposes, a fan handling 10,000-15,000 cfm is connected to the hood over the oxidized precipitate hopper and to a hood over the mill feed screw discharge point. The dust laden air is delivered to the base of a water irrigated wooden scrubbing tower mounted over a concrete sump from which the water is recirculated by means of a pump while the settled pulp is withdrawn at intervals and pumped to the leach tank (Stage 5).

FIG 2—Cell room.

5. Leaching and Purification

Variations in the sulphuric acid content of the leach solution are made from time to time in order to hold both the cadmium content and the volume of the cell feed circuit reasonably constant.

If both are about normal, leaching is done with normal cadmium cell spent electrolyte but if the cadmium content is low, the cell spent electrolyte is fortified 10 to 20 g sulphuric acid per liter. If the volume needs increasing, approximately 600 gal of spent electrolyte are supplemented with 800 gal of water and the whole acidified to 150 g sulphuric acid per liter.

In all cases the volume is 1400 to 1500 gal, and the subsequent leaching operation is the same.

Leaching of the ground cadmium precipitate pulp is carried out in a mechanically agitated lead lined tank, having a working capacity of 2400 gal and ventilated by the suction fan mentioned in Stage 4.

The desired volume of leaching solu-

tion having been run to the leach tank, pulp from the storage tank is charged until the acidity of the solution is approximately, but not less than 10 g sulphuric acid per liter.

A sample of the pulp is filtered and tested for copper by the sodium-sulphide method (see Appendix 2) and if an excessive amount of copper is present, it is reduced by the addition of unoxidized cadmium precipitate.

Leaching is continued until the acidity is reduced to 1-2 g sulphuric acid per liter when tests are made for copper and arsenic (Gutzeit's Test) and if present, more unoxidized precipitate is added. Agitation is continued for 1 hr after copper and arsenic have been reduced to 0.5 and 0.1 mg per liter respectively and if, after neutralizing with hydrated lime, a further test for arsenic is found satisfactory, the pulp is pumped to a Kroog filter press fitted with 36 by 36 by 1½ in. thick frames and plates.

The filtrate is bypassed to the leach tank until free from solid particles as indicated by filtering 500 cc through filter paper and when clarity is satis-

factory the filtrate is diverted to one of two lead lined wooden storage tanks each of 3200 gal capacity, where, if necessary, water is added to reduce cadmium to the desired content of 150 g per liter.

By discarding spent electrolyte to the original cadmium-copper precipitate leach and rebuilding the circuit with fortified spent electrolyte and water leaches the impurities are controlled to 30-40 g zinc, 0.7-0.8 g iron and 30-35 mgm chlorine per liter.

The residue collected in the Kroog press during filtering of the cadmium leach pulp, is returned to the cadmium-copper precipitate mixer (Stage 1).

6. Electrolysis

The cell room contains 20 cells arranged in five rows of four cells, each of which is of 3 in. timber, lined first with 8 lb lead and then with 2 in. of a 40 pct sulphur—60 pct sand mixture which has given good service as only 2 linings have failed in 25 yr. Internal dimensions of the cells, which have a volume of 208 gal, are 5 ft square and 2 ft 6 in. deep while the cross-section is semi-rectangular.

The lead of the 10 half-round, 23 in. radius anodes contains 0.01 pct silver to give added rigidity and extend the 4 yr life to 5 yr.

Mounted on a 3 in. diam mild steel shaft and separated at 5½ in. spacing by rubber covered aluminum sleeves are 9 aluminum cathodes, 4 ft diam and ¼ in. thick, each of which has a submerged surface area of 8 sq ft and lasts 7 to 8 yr. To enable the stripped cadmium sheet to be readily broken into four conveniently sized quadrants, each side of the cathode is radially grooved at 90° spacing to a depth of ⅜ in. Before assembly, each cathode is given a matte surface by scrubbing with a steel wire brush and sandstone.

Once each year the cathode assembly is dismantled, inspected, cleaned and, if necessary, faulty parts replaced.

Cathodes are rotated at 10 rpm by suitably driven link chains through gearing from which the cathode assembly may be disengaged without stopping the driving mechanism. Electrically the cells are arranged in series and current is supplied by two motor driven parallel connected generators rotating at 960 rpm and each capable of supplying 650 amp over a range of 25 to 70 volts.

Anode bus bars of 1¼ in. square copper are arranged to give the anode head bars an edge contact and between adjacent cells is a hinged section for short circuiting a cell when cathode assemblies are removed for stripping.

The series circuit is made complete by means of a 9 in. diam brass collector keyed to the cathode shaft and con-

tacting brushes connected by copper cable to the following anode bus bar.

Cell voltage is approximately 3.5 volts per cell.

Feed solution containing 150 g cadmium per liter gravitates from the feed storage tanks through iron pipes of uniform length flanged together for ease of cleaning.

Each cell has a separate feed pipe through which the rate of feed is controlled to hold the acidity of the cell solution at 85–90 g sulphuric acid per liter. Titrations with caustic soda using Congo Red indicator are made every four hours.

Spent overflows from each cell to a launder common to each row and gravitates to a storage tank.

Glue solution containing 0.14 lb glue per gal is added every four hours at a rate equivalent to 2½ to 3 lb per ton cadmium deposited. During deposition, the cadmium surface tends to roughen by the formation of "trees" which are wiped off at intervals with a slotted wooden tool to which rubber strips are attached to make contact with each face of the cathode simultaneously. Trees are cleaned from the cells monthly and returned to the tube mill grinding the original cadmium-copper precipitate.

Stripping periods are either 48 or 96 hr depending on the current density demanded by production. When the current density on the immersed cathode surface is between 10 and 12 amp per sq ft quite a reasonable current efficiency is obtained and the deposit adheres to the cathode, but, when the current density is higher, the stripping period is reduced to 48 hr as beyond this time the current efficiency is found to decrease and the deposited cadmium sheets tend to become detached.

The production of cadmium is not regular owing to variation in the amount of incoming cadmium, consequently both the number of cells used and the current density are varied, but it is aimed to operate at 10 to 12 amp per sq ft; however, at times a higher density is necessary. When the deposit is about to be stripped, the cell concerned is short circuited by means of the hinged section of the anode bus bar, hooks suspended from a bridge of convenient length are attached to fittings on the cathode shaft and the whole cathode assembly is lifted by means of a travelling chain block and lowered on to trestles at the end of the cell row.

The deposit is removed by means of stripping knives, broken into quadrants, stacked almost vertically in

portable racks, weighed and transferred to the melting section.

Before returning the assembly to the cell, each aluminum cathode is hosed, scrubbed with a stiff bristle brush and, if necessary, given a light rubbing with sandstone. (Fig 2.)

7. Melting, Casting and Packing

The cadmium sheets are melted, under a cover of molten rosin, in an oil fired cast iron pot, having a capacity of approximately 2500 lb cadmium.

The molten cadmium is handled from the pot to the molds in a mild steel ladle, the pouring spout of which is in the form of a pipe reaching almost to the bottom to prevent dross or flux entering the mold.

Cadmium is cast in various shapes for commercial purposes. (See Appendix 3 and Fig 3.)

Molds are either lubricated with stearin or No. 3 shell grease or sprayed with a fine mist of dilute sulphuric acid in order to give a clean bright surface to the castings which after inspection are packed in Tasmanian oak cases in which are inserted sheets of waxed paper and cardboard to keep the castings from contact with the wood.

Each case is banded with ¾ in. wide banding iron and stamped with particulars of type of casting, gross and net weights, lot and case numbers.

Periodically dross is ladled from the surface of the molten cadmium in the melting pot into mild steel trays and after cooling and weighing is ground in a Berdan grinding pan from which a stream of water carries off the slime to a settling pond, the overflow from which passes into the cadmium-copper precipitate pulp circuit.

The dross slime, collected in a settler,

FIG 3—Cadmium castings.

is fed to one of the zinc plant roasting furnaces and eventually returns, via the zinc circuit, to the cadmium plant.

Clean cadmium prills are removed from the pan, dried, weighed and remelted.

It is planned to replace the rosin flux with one of three parts ammonium chloride and eight parts zinc oxide which, in addition to enabling all cell trees to be remelted direct, will dispense with grinding and the return of the dross slime through the zinc circuit and as a result cadmium losses will be reduced.

The melting furnace is enclosed in a mild steel hood from which rosin vapor is exhausted, but before being discharged to atmosphere, passes in series through three vertical, wire packed mild steel cylinders in which approximately 60-70 pct of the rosin is condensed for further use.

Appendix 1

COPPER TEST—CADMIUM-COPPER PRECIPITATE LEACH

Reagent

Standard comparison solution containing 0.5 gpl copper.

Test

Place 100 cc of standard solution in one comparison tube and 100 cc of filtered leach solution in a similar tube. Compare the blue color against a white background.

1. If leach solution is less blue than the standard but is still perceptibly blue, the leach can be finished.
2. If no blue is perceptible add sulphated copper residue in 100 lb lots until the standard blue is obtained.

3. If the leach solution blue is more intense than that of the standard solution the excess copper must be removed by zinc dust and the quantity

required is estimated as follows:

Determine the quantity of filtered solution which, when diluted to 100 cc with water will match the blue of the standard solution. The quantity of zinc dust required per 1000 gal of leach can be determined from the following formula:

$$\text{Zinc dust per 1000 gal} = \frac{V}{100} \left(\frac{100}{2T} - 0.5 \right)$$

T = Vol. solution (cc) used in test.

V = Vol. leach solution in the leach tank.

Appendix 2

COPPER TEST—CADMIUM PRECIPITATE LEACH

Reagent

Sodium sulphide solution (saturated).

Test

Take 100 cc of filtered leach solution in a stoppered bottle, add 5 drops of sodium sulphide solution, shake vigorously and filter.

The color of the precipitate on the paper is compared with a standard and must be inspected by the shift boss before filtering is permitted.

Electrolytic Zinc at Risdon, Tasmania. Major Changes Since 1936

S. W. ROSS*

Introduction

IN 1936 a description of the plant (Fig 1) and process employed by the Electrolytic Zinc Co. of Australasia Ltd. for the recovery of zinc from zinc concentrate by the electrolytic process was prepared.†

During the twelve years which have elapsed since the preparation of the earlier paper, several major changes in the metallurgy of the process have been introduced. It is the purpose of the present paper to give a general description of these changes and thus to bring up to date the description of the plant and process.

Summary

The major changes in Risdon practice since 1936 have been:

1. Replacement of two stage roasting by a preliminary roast followed by the flotation of all the leach residue and the roasting of the flotation concentrate.

2. Screening of all calcine fed to the pachucas.

3. Continuous leaching of calcine and improved classification of pachuca discharge.

4. Close control of hydrogen ion concentration during purification for iron removal.

5. Recovery of cobalt as a good grade oxide.

6. Production of part of the zinc output in the form of "four nines" metal (99.99 pct purity).

7. Closer spacing of electrodes thus increasing the potential output of cathode zinc per cell by 50 pct.

Changes which are in prospect and for which construction work is proceeding at the present time involve the starting up of:

1. Two suspension roasters.

2. A contact acid plant to produce

150 tons† of acid per day and replacing the existing Mills Packard chamber plant.

3. Extra power station capacity to permit greater current flow to existing cell room units. This will increase the output of cathode zinc from about 245 to 290 tons per day.

Plans for the future envisage the building of an ammonium sulphate plant, the first unit of which will produce about 50,000 tons per year, and improved treatment of zinc plant residue for the recovery of zinc, lead and other metals.

At the end of this paper tables of metallurgical data are presented relating to the year ending June 30, 1948.

Details of Changed Practice Output

In 1936 the production of cathode zinc amounted to about 200 tons per day. This has since been increased to about 245 tons per day while plant extensions are practically complete which will permit of an output of about 290 tons per day in the near future.

Roasting Division

ROASTING POLICY

A major change has occurred in the roasting policy. Twelve years ago the method in use was to carry out a two

stage roast in the first stage of which sulphide sulphur was reduced to about 6 pct. The pre-roast calcine was re-roasted in modified Leggo furnaces using coal as fuel, sulphide sulphur being reduced to about 0.8 pct. The whole procedure was described on pp. 482-491 of the earlier paper.

Although this roasting procedure had certain advantages it possessed some distinct disadvantages. For instance, it appeared uneconomical to heat up the entire input of pre-roast calcine to roasting temperature by the expenditure of fuel in order to oxidise a few per cent of sulphide sulphur. It was argued that if the pre-roast calcine were leached and a process could be developed for the recovery of a zinc sulphide concentrate from the leach residue, this concentrate, small in weight compared with the pre-roast calcine, would probably roast autogenously, thus virtually eliminating the expenditure of fuel as well as greatly increasing the weight of sulphur oxidised per square foot of furnace hearth area.

The obvious method of producing a suitable concentrate from leach residue was by flotation. It will be recalled (see p. 495 of the earlier paper) that when two-stage roasting was practised the leach residue was classified, the granular fraction was ground and floated while the slime fraction was thickened, filtered and dried ready for shipment to a lead smelter. This process worked quite successfully. However, when trials were made of leaching a calcine carrying several per cent of sulphide sulphur the granular fraction still floated well, but the slime fraction carrying 8-10 pct sulphide sulphur yielded very poor results when subjected to flotation. This fact held up the application of "pre-roast" leaching for many years. However, successful flotation of the slime fraction of leach residue was finally achieved and in August 1940 the slime flotation plant began operation, while the leach-

† Throughout this paper the long ton of 2240 lb and the Imperial Gallon are used.

† W. C. Snow: *Electrolytic Zinc at Risdon, Tasmania, AIME Trans.* 121, 482.

FIG 1—General view of works.

ing of pre-roast calcine became an accomplished fact. A description of the flotation section will be given later in the present paper. Calcine leached at the present time carries from 5–6 pct sulphide sulphur while the mixture of concentrates from the granular and slime flotation sections carries about 22–24 pct sulphide sulphur. This mixed concentrate is roasted for the most part in modified Skinner furnaces.* The flotation tailing, carrying 1.5–2.5 pct sulphide sulphur, is filtered and dried and becomes the final zinc plant residue. The loss of sulphide sulphur in residue is little higher than it was when two stage roasting was practised.

It is not proposed to set out the arguments of single stage roasting to low sulphide sulphur versus the present method of roasting with intermediate flotation. However, it should be stated that the present method permits of high roasting rates and in some of the newer furnaces an oxidation rate of 12–13 lb sulphur per square foot of hearth area per day has been achieved without the use of any fuel. With a very small fuel addition (less than 0.5 pct of oil) the figure has risen to 14–16 lb.

* See contemporary paper, J. A. B. Forster: Autogenous Roasting of Low Grade Zinc Concentrate in Multiple Hearth Furnaces at Risdon, Tasmania.

CALCINE SCREENING SECTION

The introduction of continuous leaching, described later in this paper, made it imperative to screen the calcine on its way to the Leaching Division. Preliminary trials of continuous leaching when using unscreened calcine were unsatisfactory because many of the larger lumps would not move from pachuca to pachuca and accumulated in the first and second units of the series. A plant for the screening of all calcine entering the Leaching Division was, therefore, built and this has removed the trouble.

The screening station consists of two vibrating screens each 8×3 ft and fitted with $\frac{1}{4}$ in. wire mesh. The oversize falls to a bin and is fed intermittently to a swinging arm breaker. A bucket elevator returns the crushed oversize to the screens.

Leaching and Purification Division

LEACHING

The leaching of calcine and the purification of the resulting solution were described fully in the earlier paper (see pp. 491–510). No modifica-

tion of the fundamental principles of this division has occurred but many important changes have taken place in details.

The batch leaching of calcine was described in the earlier paper. Although quite successful in operation, batch leaching employs a relatively big labor force, it uses the pachucas inefficiently in that much lost time occurs in filling and emptying while the discharge of pulp at a low level loses head and under Risdon conditions makes improved classification of pachuca discharge difficult. These considerations coupled with the somewhat restricted space available for building new pachucas for increased production led to the introduction of continuous leaching in 1945.

Ten pachucas, each 12 ft diam and 34 ft stave and arranged in two rows of five, were previously employed in batch work (nine in 1936). These have been so connected that all ten may be used together if so desired, but any one or more can be cut out for repairs. In normal practice the ten units are divided into two groups of five each and one set only is in use at a time. It has been found that five pachucas, used in continuous flow, leach as well as ten employed on batch work.

Screened calcine enters a small bin of

80 tons capacity which feeds an 18-in. belt running centrally above and between the two rows of pachucas. From this belt calcine is fed continuously by means of a tripper to the head pachuca while spent solution from the electrolytic division is fed to the same pachuca.

At the top of each column and placed to one side is a swinging launder so arranged that it picks up part of the discharge from the top of the column and transfers it to a short launder feeding the next pachuca. This equipment permits the coarser particles rising in the column to be transferred to the next pachuca at the same time maintaining the same pulp level in all pachucas of the series. The discharged pulp flows to a launder placed beneath the operating floor and running between the two rows. From time to time scuttling of one or more pachucas becomes necessary and a low level launder—used previously for batch leaching—takes the discharge.

The flow of solution through the pachucas for the present output of about 245 tons of cathode zinc per day amounts to about 800,000 to 1,000,000 gal per day while 600–700 tons of calcine is leached. The spent electrolyte carries up to 100 g acid per liter and this is reduced to 1.5–2.0 g per liter before discharge.

Continuous leaching has proved advantageous in that it is simpler, saves labor, uses 35 psi air in place of 90 lb air, the equipment is utilised more efficiently while improved classification and flotation results have been made possible.

CLASSIFICATION AND THICKENING OF PACHUCA DISCHARGE

The classification of pachuca discharge has been improved by the addition of a V shaped box 42 ft 9 in. long, 10 ft wide at the top and 10 ft deep. The pachuca discharge enters at one end at the top and flows the length of the box. The fine fraction of the solids passes over the lip and enters five 50 ft diam by 15 ft stave Dorr thickeners. The granular fraction, discharged from the bottom of the V shaped box through six spigots, is dewatered in six duplex Dorr classifiers (see item 2 p. 494 of the earlier paper). The underflow from the classifiers is delivered to the granular flotation section while the overflow from the classifiers joins that from the V box on its way to the thickeners, where the pulp is thickened to a specific gravity of about 1.8. The

thickener underflow is elevated to pulp holding tanks whence it is delivered to the slime flotation plant.

FLOTATION OF LEACH RESIDUE

The granular flotation section described on p. 495 of the earlier paper remains unchanged in principle but has been enlarged, while improved classification has been achieved by the addition of a 12 ft diam cone dealing with the tailing. The underflow from the cone is dewatered in a small simplex Dorr classifier and returns to the tube mills for regrinding. The overflow from the cone goes to the five primary thickeners and so granular tailing normally joins the feed to the slime flotation section.

The slime flotation section consists essentially of three main parts, pulp preparation, flotation, and thickening of concentrate and tailing.

Pulp preparation consists of two main steps:

1. A 12 ft diam \times 12 ft stave tank mechanically agitated receives the slime pulp from the leaching division. This tank is normally kept full. Spent electrolyte is added to maintain an acidity of about 1.75 g per liter. Finely ground manganese cell mud is added. The supply of pulp, acid and manganese dioxide is more or less continuous to this tank. An air lift elevates the pulp to a bucket feeder which consists of eight stainless steel buckets attached to a 3 ft 6 in. diam wheel. The discharge from the buckets is divided by a movable cutter, one part going forward for flotation and the other part returning to the pulp tank. In this way a continuous and constant feed rate is maintained.

2. The discharge from the bucket feeder enters the first of five air agitated processing boxes each 4 ft square. Finely divided limestone pulp is fed to the first box for neutralising excess acid. Then cresylic acid and eucalyptus oil are added and finally the pulp is diluted with circuit solution to a pulp density of about 3–3.5 lb solids per gallon. A pulp density recorder controller maintains the pulp at the required specific gravity.

The processed pulp then goes forward to the flotation boxes. There are sixteen boxes arranged in two rows of eight. Each box is 3 ft 6 in. \times 3 ft 6 in. \times 5 ft 2 in. deep. The impellers, 18 in. in diam, are made of stainless steel and revolve at 370 rpm. Each pair of impellers is driven by a single vertical

12 hp motor, while air from a Connorsville blower is supplied through an adjusting valve to each box. Each row of eight boxes has a common pulp level since each partition between boxes has an aperture 2 ft wide \times 6 in. deep cut 8 in. from the bottom. The froth level is controlled by inserting riffles in slots. No mechanical scraping is necessary since the froth flows very freely.

The sixteen boxes are divided into three groups, namely, five rougher concentrate, three cleaner concentrate and eight scavenger. Potassium xanthate is added to the pulp leaving the rougher boxes and entering the scavenger boxes.

The tailing flows to two 50 ft diam \times 15 ft stave Dorr thickeners. The overflow is returned to the flotation circuit while the thickened pulp is filtered and dried as described on pp. 496 and 497 of the earlier paper. Oil has replaced coal for firing the driers.

The combined concentrate from the two flotation sections is thickened in two 50 ft diam \times 15 ft stave Dorr thickeners. The overflow is returned to the main zinc plant circuit while the underflow is filtered in two six-leaf 8 ft 6 in. diam disc filters. The discharge from these filters is not washed and is forwarded by belt conveyor for roasting.

It has been found that the zinc content of the circuit solution in the slime flotation section is of importance and an endeavor is made to keep zinc in the range 80–90 g per liter. This is done by bringing washings and other low zinc tenor liquors into the flotation section and using them for pulp dilution.

IRON PURIFICATION

The overflows from the five primary thickeners dealing with pachuca discharge combine and the solution goes forward for the removal of iron, silica, arsenic and antimony, by the addition of finely divided limestone. This procedure was described on pp. 497 and 498 of the earlier paper and the basic principles remain unchanged. Considerable refinement in detail has taken place however, and this has effected a marked improvement in the filtering properties of the precipitate while the effectiveness of purification has been increased considerably.

In 1936 there were four 28 ft diam \times 12 ft stave agitators in series. An extra agitator has been added and each of the first three in the series has been divided into two by building a partition across

a diameter in order to reduce the effect of short circuiting. The first agitator receives thickener overflow at about 1.5 to 2.0 g acid per liter. Here ground manganese mud is added for the oxidation of iron. During the leaching of preroast calcine up to 1.0 g iron per liter is dissolved and part of this is reduced by sulphides to the ferrous state and up to 300–400 mg of ferrous iron per liter may be present. The bulk of this is oxidized in the first agitator.

The conditions in the second agitator of the series are critical and it is here that considerable improvement has occurred. It was discovered that both the physical state and the chemical composition of the precipitate resulting from the addition of limestone are profoundly altered according to the hydrogen ion concentration at which precipitation occurs. It has been determined that if the pH of the pulp in the precipitating tank is maintained at a figure greater than about 4.0 the physical state of the resulting precipitate is such that it filters rapidly while the iron is present almost wholly as ferric hydroxide with but small formation of basic ferric sulphate.

The effect of this procedure on the filtering rate of the ensuing pulp is remarkable. If limestone is added to the acid solution so that the pH slowly rises to the critical figure the time of filtering the pulp under otherwise similar conditions will be about five times as long as it is if the pH is maintained at about 4.0 during precipitation. Similar results are obtained if the neutralising agent is finely ground calcine instead of limestone.

The control of pH is achieved by the continuous addition of finely ground limestone and the intermittent return to the purifying tank of every second primary filter cake. A pH indicator and also a recorder have been installed and it is proposed to add a controller to the recorder.

No material change has occurred in the amount of silica removed during iron purification but the recognition of the part played by silica during purification has been of importance. In the course of leaching traces of germanium are dissolved, and, if this element is not removed almost completely, it increases the reversion of cadmium during the filtration of copper cadmium precipitate and reduces current efficiency during subsequent electrolysis. It is believed that the presence of at least 1.0 g per liter and preferably about 1.3 g per liter of silica in the solution

entering the iron purification tanks is effective in controlling germanium.

The filtration of iron precipitate was described in detail on pp. 498–501 of the earlier paper. The number of leaves per filter basket has been increased in the ratio of five to four while a rest period in hot water has been introduced to remove incrustations of gypsum from the canvas. These factors coupled with the greatly improved filtering properties of the precipitate have enabled the section to handle with ease the solution flow equivalent to 245 tons of cathode zinc per day, whereas previously, difficulty was often encountered when the output was only 200 tons. It is anticipated that existing equipment will handle without difficulty the solution flow when output increases to 290 tons of cathode zinc per day.

COPPER CADMIUM PURIFICATION

The removal of copper and cadmium was described on p. 501 of the earlier paper. The section has been enlarged somewhat and the general results improved. Eight purifiers are now employed and filtration takes place in 3 × 3 ft Dehne presses as previously. The solution for purification now contains about 90–120 mg copper and 150–180 mg cadmium per liter. The zinc dust charge is normally 250–300 pct of theoretical requirements.

The filtration of the discharge from the purifiers has been improved by feeding both ends of the presses which are now fitted with 68 frames 1½ in. thick built up from mild steel. The improved feeding arrangement coupled with the 1½ in. frames permits the filling of a press in approximately 12 hr. Control of germanium during iron purification, quicker filling of presses and a greater excess of zinc dust coupled with a constant watch by shift chemists on the cadmium content of press filtrate, have combined to produce a purified solution carrying 1.5–2.5 mg cadmium per liter.

The filter cake is treated for the recovery of metallic cadmium and of copper in the form of a copper rich residue in a separate plant.*

COBALT PURIFICATION

The method of removing cobalt from solution was described in detail on pp.

501 and 502 of the earlier paper. No change, except in minor detail, has occurred in the method of purification during the ensuing twelve years.

COBALT OXIDE PLANT

A major change has taken place in the method of disposing of the cobalt precipitate which was previously wasted. Many attempts were made to find uses for this precipitate and to recover economically valuable by-products from it, but all such early attempts ended in failure.

The precipitate after filtration is a mixture of cobalt nitroso beta-naphtholate, gypsum, basic zinc sulphate and unconsumed slaked lime, mixed with zinc sulphate solution. It was discovered that the cobalt nitroso beta-naphtholate would float and if conditions were right, a relatively high grade concentrate could be produced. A plant was, therefore, built and has operated successfully since 1936. One of the features of this process is that the concentrate froth is produced quite readily in the absence of any addition agent.

The cobalt precipitate pulp is transferred from the purification section by pulping it with water and pumping it to the cobalt oxide plant. Two mechanically agitated tanks 9 ft diam × 11 ft stave receive the pulp. These tanks are used alternately, one receiving the pulp one day and the other receiving it the next day. When the day's output of precipitate is transferred, sulphuric acid is added until the acidity reaches about 3 g per liter. Basic zinc sulphate and calcium hydroxide are consumed during a short period of agitation. The pulp contains about 2½ lb of solids per gal and is pumped to the first of a row of ten flotation boxes each 3 ft × 2 ft 9¼ in. × 5 ft deep. The ten boxes all have a common pulp level since the partitions between boxes do not extend to the bottom and leave a gap of 3 in. On the floor of each box is a canvas aerator stretched over a rectangular frame of 1¼ in. copper pipe. Air is supplied to the aerator at a pressure of 1½–2½ psi while the froth level is controlled by riffles fitted into slots. The first box of the series is used as a digester and returned circuit solution is added to bring the pulp density to about one pound per gallon. The next six or seven boxes are used for concentrate production while the last two or three make a middling which is returned to the feed.

* See contemporary paper, G. H. Anderson: The Recovery of Cadmium from Cadmium Copper Precipitate—Electrolytic Zinc Co. of Australasia Ltd.

The tailing is normally a milky white suspension of fine gypsum crystals in zinc sulphate solution.

The process is very sensitive to the volume of air supplied to the aerators and the flow of concentrate froth must be extremely gentle otherwise gypsum is entrained in it. A normal calcium content of the concentrate is about 0.02 pct but it is very easy to multiply this many times by the use of too much air. Another impurity of importance is iron. If iron escapes precipitation in the iron purification section some of it is later precipitated along with cobalt. The flotation of cobalt precipitate does not differentiate between iron and cobalt so that virtually all the iron present in the precipitate appears in the concentrate.

The concentrate flows to a 9 ft diam \times 9 ft stave holding tank whence it is pumped to a Moore filter. The basket consists of six leaves each 4 ft \times 3 ft 6 in. After filtration the basket is transferred to a washing tank where thorough washing removes most of the water soluble zinc. The cake is blown off to a hopper from which it is fed to an oil fired hand rabbled reverberatory furnace 20 ft long \times 4 ft wide where the organic material is burned off, and a final product of reasonably pure cobalt oxide is discharged from the furnace. This is placed into steel drums ready for the market. During the war years some cobalt sulphate and metallic cobalt were produced for special purposes.

SOLUTION COOLING

The plant for the cooling of purified solution prior to its being pumped to the electrolytic division which was described on p. 504 of the earlier paper, has been extended by the building of a second cooling tower similar to the one described previously. The two towers are used alternately so that during the cleaning of one tower the other is in use.

Electrolytic Division

The electrolytic division was described in detail on pp. 511-519 of the earlier paper. Basically, the same procedure is still employed but some quite important modifications have been introduced.

FOUR NINES ZINC

The specification of the Standards Association of Australia for zinc base

die casting alloy sets an upper limit for lead of 0.007 pct. Attempts at Risdon over many years failed to produce zinc conforming to this specification. The best results had been obtained with 1 pct silver lead anodes but the zinc still contained 0.01 pct lead or even more. During the war a considerable demand for high quality die castings developed and renewed efforts were made to meet the specification. Following a suggestion made by Mr. W. H. Hannay of The Consolidated Mining and Smelting Co. of Canada success was achieved by the simple expedient of cooling the electrolyte in cells fitted with 1 pct silver lead anodes to about 28°C. Many thousands of tons of zinc containing about 0.005 pct lead have now been produced by this method and have been used for the production of die casting alloy. There is no production of ingot zinc of this very high grade since all cathodes not used for the manufacture of die casting alloy are melted with the ordinary make of plant zinc. The anodes used are not perforated and conditions of electrolysis are standard except in regard to temperature. Experiments in which the temperature was reduced to 20°C showed no further improvement in the lead content of zinc.

CLOSER SPACING OF ELECTRODES

In 1936 the cells in the four big units contained 34 anodes and 33 cathodes while the current flow was nominally 12,000 amp. The spacing of anodes center to center varied between 4 in. and 3½ in. in the various units. The urge for increased power efficiency and later

for increased output focussed attention on the closer spacing of electrodes. A suitable double cone porcelain spacing insulator was developed and two of these were fitted to each anode. (See Fig 2). In this way it was found possible to insert 45 anodes and 44 cathodes into each cell at 3 in. spacing. The current flow can be increased to 18,000 amp and the output from a single unit increased from about 46 to about 69 tons per day.

At the present time the four big units have all been fitted with rolled copper bus-bars capable of carrying the increased current. However, only two units are as yet supplied with the full power input. The other two units will be supplied as soon as a new converter station, now under construction, is completed.

ELECTRODES

The size and shape of electrodes are virtually the same as they were in 1936 except that now plain ¼ in. aluminum sheets are used as cathodes.

Twelve years ago the life of a cathode was extended by attaching protective strips of aluminum above solution level. This was effective because maximum corrosion occurred about 1½ in. above solution level. In recent years solution line corrosion has increased markedly possibly related to an increase of fluorine in the electrolyte from about 15-20 mg per liter up to 30-35 mg per liter. Protective strips which give no benefit at the solution line have therefore been discarded but cathode cost per ton of zinc has increased considerably.

Trials of re-rolled used cathodes have

FIG 2—Anode spacing insulator. Glazed porcelain.

FIG 3—Hoist in action.

been made with only moderate success.

Anodes now contain 0.012 pct silver. This addition has been made to increase the stiffness and to reduce the need for anode straightening. This small addition probably is responsible for a reduction in the lead content of normal cathode zinc to a figure of about 0.012 pct. An interesting minor modification has been made in the treatment of new anodes prior to placing them in the cells. It was discovered that if the anodes were painted with a slurry of cell mud while they were still hot after casting, the conditions of electrolysis were much improved during the first two or three stripping periods. Prior to the introduction of this practice current efficiency was low during the first few stripping periods.

COOLING OF ELECTROLYTE

The adoption of closer spacing and greater current flow has called for more cell cooling. There is not room for more than about four cooling coils per cell and in these circumstances the temperature of the electrolyte during the hotter months of the year tended to be unduly high. Experimental work has indicated that the greatest yield of

cathode zinc per unit of power occurs when the temperature of the electrolyte is about 32–33°C. In practice an endeavor is made to keep the temperature below 35°C.

The demand for a greater extraction of heat from the cells stimulated an investigation into the design and cleaning of the cooling coils described on p. 514 of the earlier paper. The outstanding result of this investigation was the recognition that even when cleaned thoroughly by hand scraping and brushing, a coil quickly lost up to one half of its effectiveness due to the formation of a thin hard scale on the outer surface.

A system of electrolytic cleaning has been developed in which the coils are made cathodic in a dilute solution of sulphuric acid. An input of about 75–100 amp per coil is effective in removing adherent scale during overnight treatment. The efficiency of the coil as a heat remover has been restored to about 90 pct of that of a new clean coil and temperature control of the electrolyte is now not difficult even in the hotter months of the year.

LIFTING OF CATHODES

The hand operated chain blocks for

lifting groups of cathodes for stripping and described on pp. 514–515 of the earlier paper are still in use but at the time of writing this paper a change-over is being made to electrically operated hoists. One of these has been on trial for a long period and has proved very satisfactory. Another twelve are being installed and it is hoped to equip the whole cell room with these hoists—one hoist for every three cascades. (Fig 3.)

ADDITION AGENTS

The use of about 24 mg glue per liter and 10 mg beta naphthol per liter, referred to on pp. 514, 516 and 517 of the earlier paper is still maintained.

It is no longer necessary to add antimony since improved technique in solution purification appears to have overcome many of the difficulties previously experienced during electrolysis. Current efficiency averaging about 92 pct is maintained with a 72 hr stripping period.

Melting and Casting Division

This operation was described in detail on pp. 519–526 of the earlier paper. The major change introduced during the intervening years has been the abandonment of coal firing and the use of oil in its place. No leaded zinc has been produced for some years.

Metallurgical Data

The following tables refer to average figures for a four weekly period during the year ended June 30, 1948.

Feed solution was taken for analysis in June, 1947. During the year ended June 30, 1948 average cathode zinc output was 211.2 tons per day although it had risen to about 245 tons at the close of the year.

Roasting Division

The data relevant to this division will be found in contemporary paper by J. A. B. Forster.

Acknowledgment

The author wishes to express his appreciation to the Directors and Management of the Electrolytic Zinc Co. of Australasia Limited for permission to publish this paper. Also, his thanks are due to those who have helped in various ways in its preparation.

The Hardenability Effect of Molybdenum

J. M. HODGE,* J. L. GIOVE,* Members AIME, and R. G. STORM*

Introduction

THE hardenability effect of molybdenum has been evaluated by a number of investigators, including one of the present authors.^{1,2,3,4,6} Considerable discrepancy exists, however, among the results of these various investigators, and two of them, Brophy³ and Kramer,⁴ have indicated that the apparent hardenability effect of molybdenum would vary, depending upon the other alloying elements in the steels being considered. The results of previous, unpublished work conducted at the Duquesne Works Laboratory of the Carnegie-Illinois Steel Corporation also have indicated significant differences in the hardenability effect of molybdenum in nickel and in chromium steels.

The present investigation was undertaken in an effort to establish the mechanism governing this difference in the hardenability effect of molybdenum. This work involved both end-quench hardenability and isothermal transformation tests on two series of steels of varying molybdenum content. One steel contained 3 pct nickel and the other 1 pct chromium. It was hoped that such studies would shed further light on the mechanism of this behavior.

Materials and Experimental Work

MATERIALS

The chemical compositions of the steels used in this investigation are shown in Table 1. These steels were furnished by Battelle Memorial Institute in the form of 100-lb induction furnace ingots. The top half of each ingot was forged to 1 $\frac{3}{8}$ -in. square billets and then rolled to 1-in. round bar stock for isothermal transformation studies.

tion studies. The bottom half of each ingot was forged into approximately 1 $\frac{1}{4}$ -in. rounds for end quench tests. All of the steels were normalized from 1650°F and tempered at 1100°F before machining to end quench or isothermal samples.

END-QUENCH TESTS

Standard 1-in. diam end-quench tests were made on each of the steels. The test bars were austenitized at 1600°F for 30 min., quenched in a standard Jominy jig, and hardness surveys were made in all tests. The 95 pct martensite point was determined from hardness values⁵ and checked by metallographic examination. The Jominy distance values for 95 pct martensite were converted to hardenability values in terms of ideal

diameter (D_1), using a revised curve for the relationship between Jominy distance and ideal diameter. This curve was based on the cooling time from the A_1 to the bainite nose temperatures rather than on the usual criterion of half-temperature time. The cooling rates as determined by Russell and Williamson⁹ were used as a basis for this relationship. The derivation of this curve is described in detail in the appendix.

ISOTHERMAL TRANSFORMATION STUDIES

Samples for the isothermal transformation studies were quarter sectors of $\frac{1}{16}$ -in. thick slices from the 1-in. round bars. All samples were austenitized for a total time of 15 min., transferred rapidly to a lead bath for isothermal transformation, and brine quenched from the lead bath. A time of 3 sec was allowed for the sample to come to the temperature of the lead bath, and this time was not included in the isothermal transformation times.

Each sample was examined metallographically at a magnification of 100 diam. The per cent transformation was estimated by comparison with standard micrographs, and the values were plotted against time on log/log coordinate paper. At least 4 and as many as 10 points were plotted for each steel. A line was drawn through the points for each steel, and the times for 5 pct transformation were obtained from the plot for each steel.

Isothermal transformation diagrams in terms of 5 pct total transformation, covering the temperature range of 800 to 1200°F, were determined in this manner for an austenitizing temperature of 1600°F. The times for 5 pct transformation at the bainite nose for austenitizing temperatures of 1800 and 2000°F were also determined in the same manner.

These times for 5 pct total transformation

FIG 1—End quench hardenability curves for a series of 3 pct nickel steels.

mation at the bainite nose were converted to hardenability values in terms of ideal diameter by multiplying them by a factor of 1.5 and correlating the results with the cooling times from the A_1 to the bainite nose temperature in an ideal quench. This method is described in detail in the appendix.

Results and Discussion

The results of the hardness surveys on the end-quenched samples, austenitized at 1600°F, are shown in Fig 1 and 2. The 95 pct martensite points, determined microscopically, are also indicated on these curves. The location of this microstructure corresponds in general with the hardness value for 95 pct martensite as reported in Ref. 5. The hardenability factors for molybdenum, determined by dividing the ideal diameters of the steels containing molybdenum by the ideal diameters of those containing no molybdenum, are shown in Fig 3. It is evident that the hardenability effect of molybdenum is much more pronounced in the nickel than in the chromium steels. It is, perhaps, significant that the hardenability factors for molybdenum in the

chromium steel correspond approximately to those originally determined by Grossmann,¹ which are also shown.

The microstructures at the 95 pct martensite point on the end-quench test samples of each series containing 0.18 pct molybdenum are shown in Fig 4 and 5. The nonmartensitic products are predominantly bainitic in both steels. Some acicular ferrite is to be noted, however, and the nickel steel shows somewhat more of this apparently ferritic constituent.

The isothermal transformation studies were undertaken principally to determine if the hardenability differences noted in the results of end-quench tests reflected actual differences in the rate of transformation to bainite, or if they were associated with incubation effects or differences in nucleation which occurred during continuous cooling. The results of the isothermal transformation studies from samples austenitized at 1600°F are summarized by isothermal transformation diagrams in Fig 6 and 7. It is apparent from the diagrams that the transformation rates in both the pearlitic and bainitic regions have been decreased in both types of steel by the addition of molybdenum. There are also large differences in the

FIG 2—End quench hardenability curves for a series of 0.95 pct chromium steels.

FIG 3—The hardenability effect of molybdenum in 3 pct nickel and 0.95 pct chromium steels. End quench tests.

magnitudes of these effects in the two types of steel. The molybdenum was much more effective in decreasing the transformation rates, in the temperature range 1000 to 1200°F, in the nickel than in the chromium steels.

As will be evident, this effect on the rates of transformation at the higher temperatures is not particularly pertinent to the present investigation, which is concerned with 95 pct martensite hardenability, the nonmartensitic products being predominantly bainitic. However, the large differences in the rates of transformation in the pearlitic range in the two types of steel would be very important if one were concerned with transformation to pearlitic microstructures.

There are also evident differences in the effect of molybdenum on the transformation rates at the bainite nose in the two types of steel. On converting these transformation time values to hardenability values, by the methods mentioned above and described in detail in the appendix, it is evident that these differences in the hardenability effects, as expressed by the multiplying

factors, are identical with those observed in the end-quench tests. The hardenability values for the end-quench and the isothermal transformation tests are given in Tables 2 and 3, respectively. It is apparent that, although the ideal diameters determined from the results of the end-quench tests are larger than those determined from the isothermal studies from an austenitizing temperature of 1600°F, the multiplying factors for molybdenum, calculated from the results of both tests, are substantially the same. These multiplying factors expressing

the hardenability effect of molybdenum in both the end-quench and isothermal transformation tests are plotted as a function of molybdenum content in Fig 8. Thus the hardenability effect of molybdenum and the differences in its effect in the two types of steel, as shown by the results of end-quench tests, are seen to be fully accounted for by the effect of molybdenum on the isothermal transformation rate to bainite.

Micrographs illustrating the appearance of the transformation products which formed at the nose temperature

FIG 4—(Above) Microstructure of the end-quench bar at approximately 95 pct martensite in the 3 pct nickel, 0.18 pct molybdenum steel. Picral-zephiran chloride etch. $\times 1000$.

FIG 5—(Below) Microstructure of the end-quench bar at approximately 95 pct martensite in the 0.95 pct chromium, 0.18 pct molybdenum steel. Picral-zephiran chloride etch. $\times 1000$.

after about 5 pct transformation are shown in Fig 9 and 10. These products are similar in appearance to those observed at the 95 pct martensite point in the end-quench test samples. As would be expected, however, the transformation during the continuous cooling of the end-quench test samples evidently occurred at a somewhat lower average temperature than the isothermal nose temperature.

One plausible explanation for this difference in the hardenability effect of molybdenum in nickel and in chromium steels might be that it reflects differ-

ences in the rate of carbide solution in the two steels, at a given austenitizing temperature. In order to check this hypothesis, isothermal transformation studies were made at the bainite nose temperature, using austenitizing temperatures of 1800 and 2000°F. The results of these studies are superimposed on the isothermal transformation diagrams of Fig 6 and 7, and the corresponding hardenability values as a function of austenitizing temperature are shown in Fig 11 and in Table 3. The multiplying factors expressing the hardenability effects of molybdenum

in samples austenitized at these higher temperatures are superimposed on Fig 8 along with corresponding factors for 1600°F austenitization. It can be seen that, although the transformation rates to bainite are markedly decreased by increasing the austenitizing temperature, the hardenability effect of molybdenum and the differences in its effect on the two series of steels, remains unchanged with changes in the austenitizing conditions within the temperature range 1600 to 2000°F.

The probability appears remote that the rate of carbide solution with in-

creasing austenitizing temperatures has caused these large increases in hardenability, because no undissolved carbides were observed in any of the steels after austenitizing at 1600°F. Furthermore, the increase is as marked in the nickel steel without molybdenum as it is in the chromium steel with 0.32 pct molybdenum. The increase in hardenability correlates roughly with the increase in grain size which accompanied the increased austenitizing temperature. This increase in hardenability, however, seems rather large to be ascribed altogether to the increased grain size, particularly as it is based on transformation rates in the bainite region.

Conclusions

1. The hardenability effect of molyb-

denum, based on end-quench tests of two series of steels, one with a base composition of 0.40 pct carbon and 3 pct nickel and the other with a base composition of 0.40 pct carbon and 1 pct chromium was more pronounced in the nickel steels; 0.32 pct molybdenum was about twice as effective in the presence of 3 pct nickel as in the presence of 1 pct chromium.

2. The hardenability effect of molybdenum in both steels, and the difference in its effect in the presence of nickel and chromium are quantitative reflections of its effect on the rate of transformation at the bainite nose temperature.

3. The hardenability effect of molybdenum in the presence of either nickel or chromium is unaffected by changes in austenitizing temperature over the temperature range of 1600 to 2000°F.

4. The explanation of the difference

in the effect of molybdenum on transformation rates to bainite in the presence of nickel or chromium was not apparent, but it did not seem to reflect differences in the rate of carbide solution in the two types of steels.

Appendix

CALCULATION OF HARDENABILITY VALUES FROM END-QUENCH AND ISOTHERMAL DATA

As mentioned in the body of this report, the hardenability values, as derived from the results of either the end-quench or isothermal transformation studies, are based on the cooling time from the A_1 to the bainite nose temperatures. This criterion was chosen because it permitted the isothermal transformation times at the bainite

FIG 9—(Above) Microstructure of isothermal sample at the bainite nose temperature after about 5 pct transformation in the 3 pct nickel, 0.18 pct molybdenum steel. Picral-zephiran chloride etch. $\times 1000$.

nose to be converted to hardenability values by the method developed by Grange and Kiefer.⁷ For consistency, therefore, the same criterion was used in evaluating the end-quench test results.

The correlation curves between Jominy distance and ideal diameter for the two series of steels, based on this criterion, are shown in Fig 12. The cooling time from A_1 to the bainite nose

temperatures, on which the ideal diameter values of these curves are based, were determined from the cooling rates along the end-quench bar which were recently published by Russell and Williamson.⁹ These cooling rates, plotted in terms of fractional temperature as a function of time, are reproduced in Fig 13.

In order to convert the cooling times from the A_1 to the bainite nose tem-

peratures to ideal diameter values, such cooling times for a series of cylinder sizes, assuming an infinite quench and diffusivity of 0.0099 sq. in. per sec were calculated from Russell's tables.⁸ From these times, plots correlating cooling time and ideal diameter were prepared for austenitizing temperatures of 1600, 1800, and 2000°F. These plots are shown in Fig 14, 15, and 16.

FIG 11—Hardenability as a function of austenitizing temperature in nickel-molybdenum and chromium-molybdenum steels.

FIG 12—Relationship between Jominy distance and hardenability based on cooling time from A_1 to the bainite nose temperature.

FIG 13—Cooling rates at different locations along an end quench bar quenched from approximately 1600°F. (Russell and Williamson.)

FIG 14—Relationship between ideal diameter and time to cool from the A_1 to the bainite nose temperatures. Austenitized at 1600°F.

FIG 15—Relationship between ideal diameter and time to cool from the A_1 to the bainite nose temperatures. Austenitized at 1800°F.

The relationships between the distance from the quenched end of the Jominy bar and the ideal diameter, as shown in Fig 12, are therefore based on the cooling times as determined from Fig 13, and the relationship between cooling time and ideal diameter as shown in Fig 14. The hardenability values corresponding to the isothermal transformation times at the bainite nose were likewise determined from Fig 14, 15, and 16. These isothermal transformation times were multiplied by a factor of 1.5 before making this conversion. This factor of 1.5 represents the average relationship between the continuous cooling time from the A_1 to the nose temperatures and isothermal transformation time at the nose temperature, as determined by Grange and Kiefer.⁷

A Method of Examination of Sections of Fine Metal Powder Particles with the Electron Microscope

LAURENCE DELISLE*

FIG—1 Tungsten powder particles $\times 10,000$. Reduced approximately one fourth in reproduction.

Introduction

THE aim of this paper is the description of a technique to be applied to the study of sections of metal powder particles, less than 20 microns in diam, with the electron microscope, by the replica method, using for replica a material such as formvar or parlodion.

This work originated with the study of particles of tungsten powders. Such particles were too small to be examined in sufficient detail with the light microscope. On the other hand, examination with the electron microscope of the

powders dispersed in the supporting film was not found satisfactory because: 1. It did not permit differentiating between single particles and aggregates. 2. It did not show the true outlines of the particles but only the projection of a whole surface. 3. No details appeared. For that reason it was

attempted to make replicas of sections of the particles imbedded in a mounting material suitable for polishing and etching. The method proved satisfactory for the examination of tungsten powder and was then extended to carbonyl nickel and carbonyl iron powders.

Procedure

Several mounting materials commonly used in ordinary metallography were investigated. The problem consisted in finding a mounting material

that would (1) wet the metal particles, (2) be of proper hardness to give, after polishing, a fairly smooth surface from which a replica could be stripped, (3) resist the attack of etchants, (4) be incompatible with the replica material to permit stripping.

Of the mounting materials investigated, aerotex M-3, a water soluble melamine formaldehyde plastic, was found to be the easiest to use. A thick

paste was made by mixing the powder in a little aerotex. A thin layer of this mixture was spread on a square of glass, about $\frac{1}{2}$ in. on the side, thick enough to permit easy holding during polishing. The best final surface was obtained by spreading the mixture of powder in aerotex into a film as thin as possible. Under such a condition, the aerotex polymerizes into a continuous film that seems to gain strength from the glass

backing. A thick layer of aerotex gives a porous rough surface after polymerization. Polymerization was carried out in a drying oven at 140°C for 2 hr. The specimens were then carefully polished and etched* in the ordinary man-

* Standard etchants were used as follows:
 Powder Etchant
 Tungsten 10g NaOH, 10g $\text{FeK}_3(\text{CN})_6$, 100cc water
 Nickel Merica's solution: HNO_3 (70 pct) 50cc; CH_3COOH (50 pct) 50cc
 Iron 2 pct nital
 All etchants were applied by flooding.

FIG 3—Particles of carbonyl iron powder illustrating differences in grain size. $\times 10,000$. Slightly reduced in reproduction.

ner for metallographic work through emery papers, silk cloth and velvet. The usual precautions to prevent removal of inclusions from metallographic specimens had to be observed; consequently most of the polishing was carried out on the silk wheel with alumina from Linde Air Products Co. as an abrasive. Either formvar or parlodion replicas could be stripped from the surface and shadow-cast as is customary.

Results

Fig 1 shows sections through particles of a sample of tungsten powder. The shape and microstructure of the particles are clearly visible. Evidently many aggregates actually consist of small particles sintered together; the sintering probably took place during reduction of the tungsten oxide in the preparation of the metal powder. The

resolution power of the light microscope is not sufficient to permit such an observation. Examination with the electron microscope of the powder dispersed in the supporting film also fails to indicate whether the aggregates consist of separate particles just touching one another or of particles bonded together into actually much larger particles.

Fig 2 shows sections through particles of a sample of carbonyl nickel

FIG 4—Particles of carbonyl iron powder illustrating differences in the structure. $\times 10,000$. Slightly reduced in reproduction.

powder. In this case, the large specific area of the powder is evidenced by the jagged outline of the particles. Again the resolution power of the light microscope is too low to reveal the surface condition of the particles of such a powder. Examination with the electron microscope of the powder dispersed in the supporting film would also fail to bring out the surface details of the powder or would, at least, show them less clearly than replicas of the sections

do.

Fig 3, 4 and 5 show sections through particles of a sample of carbonyl iron powder. The shape and microstructure of the particles are again clearly visible. The diversity in grain size and structure of the particles of a small sample of a powder is striking. Fig 3 illustrates differences in grain size; Fig 4 brings out differences in the structure of particles with the characteristic "onion skin" appearance; Fig 5 is a micro-

graph of the same particle as Fig 4a at a higher magnification; it emphasizes the presence of two finely dispersed constituents which are alternately in larger proportions forming concentric darker and lighter rings. The number and sharpness of the structural details visible with the electron microscope is greatly increased over those brought out with the ordinary microscope. From observations with the ordinary microscope, for instance, one might be temp

FIG 5—Particles of carbonyl iron powder. Micrograph of Fig 4a at a higher magnification. $\times 15,000$.

ted to exaggerate the occurrence of particles with an "onion skin" structure and to attribute the absence of such a structure in a large number of particles to improper etching. Really many particles consist of polyhedral grains of iron too small to be resolved with the light microscope.

Conclusions

The micrographs in this paper prove that the application of the electron microscope to the study of fine metal powders can be extended to the examination of sections of the particles. The microstructure of such particles can thus be revealed beyond the range of resolution of the light microscope. Added information can also be obtained

on the size, shape and surface condition of metal particles by a study of their cross-sections with the electron microscope over the information obtainable with the same instrument from a study of the powders dispersed in supporting films.

The Effect of Ferrite Grain Size on Notch Toughness

J. M. HODGE,* R. D. MANNING,* Members AIME, and H. M. REICHHOLD*

Introduction

THE work reported in this paper represents the first of a series of investigations of the factors governing notch toughness in ferritic materials. This paper is concerned with two of these factors, namely, the effect of ferrite grain size, and the effect of an alloy content of 3.64 pct nickel. Every effort has been made to hold other variables constant in order to isolate the effects of these two. The compositions chosen for study were 0.02 pct carbon in order to eliminate the variable of carbide distribution, one steel being a plain carbon steel and the other alloyed with 3.64 pct nickel. Both steels were fully killed with silicon, without an aluminum addition, so that the variable of deoxidation practice was held constant. Finally, all samples were water quenched from 1200°F and tempered 24 hr at 300°F in order to hold the quench aging variable constant and to decrease the tendency for grain boundary carbide precipitation.

The ferrite grain size was varied by heat treatment over the range of A.S.T.M. grain size numbers of about 2 to 6 in each steel so that the effect could be evaluated individually and the notch toughness of each steel could be compared at comparable ferrite grain sizes.

* By vacuum fusion analysis.

Materials and Experimental Procedure

MATERIALS

The materials for this investigation were obtained from Battelle Memorial Institute as 250 lb induction melts which were forged into 1½ in. square bars and then rolled into 0.6 in. square bars. Both steels were deoxidized with silicon, the aluminum content being held to a minimum. Check analyses of these materials are shown in Table 1.

HEAT TREATMENT FOR GRAIN SIZE

The grain size was varied by varying both the cooling rate and the austenitizing temperatures.

The heat treatments used and the corresponding grain size values are tabulated in Table 2.

A semicontinuous network of grain boundary carbide was observed in the microstructure of both the plain carbon and nickel steels in the as rolled condition and an additional heat treatment was necessary to eliminate this variable. Therefore, all samples were water quenched from 1200°F and tempered 24 hr at 300°F as a final treatment before testing. This heat treatment served to eliminate to a great extent the grain boundary carbide network and to hold the quench aging effect constant.

IMPACT TESTING

Standard keyhole Charpy impact tests were machined after heat treatment. A bath of acetone and dry ice was used for refrigeration of the samples down to temperatures of -94°F (-70°C) and a bath of either methylcyclohexane or isopentane, cooled by

Notes:
After above treatments all bars were heated at 1200°F for one-half hour and water quenched, and then were heated for 24 hr at 300°F and air cooled.
Numbers in parentheses under Ferrite Grain Size Number refer to the range of grain sizes present.

liquid nitrogen, was used for the lower temperatures. Wherever possible, three tests were broken at a given temperature. In the vicinity of the beginning and ending of the transition temperature range, testing was conducted in such a way as to restrict the testing interval to 10°F. The appearance of the fracture was noted on each test and was recorded in terms of the percent of the area which showed a cleavage type of fracture.

ESTIMATION OF FERRITE GRAIN SIZE

The ferrite grain size was estimated by comparison of the microstructure at a magnification of 100 with standard grain size charts. The grain size reported is the predominant grain size, as a range of grain sizes was present in most samples. The values represent an average of the estimations of three independent observers.

HARDNESS MEASUREMENT

Rockwell B hardness measurements were made on impact samples from each heat treatment.

END-QUENCH TESTS

Standard $\frac{1}{2}$ in. end-quench tests, austenitized at 1700°F, were made on each steel to study the effect of cooling rate on ferrite grain size. Ferrite grain size as a function of the distance from the quenched end of the bar was determined by metallographic examination.

Results and Discussion

MICROSTRUCTURE

Typical microstructures of the two steels after the final treatment are shown in Fig 1-4.

RELATIONSHIPS AMONG FERRITE GRAIN SIZE, NICKEL CONTENT, TRANSITION TEMPERATURE AND IMPACT VALUES

Plots of the impact values as a function of testing temperature for each of the steels at each grain size value are shown in Fig 5-17. The corresponding transition temperature was determined from each of these plots. This was defined as the middle of the temperature range over which an impact value of 40 ft-lb was obtained. These temperatures and the temperature ranges at 40 ft-lb for each of the conditions are

tabulated in Table 2. The value of 40 ft-lb was chosen as a criterion inasmuch as most of the actual test results fell either below or above this value and it therefore represents the point at which the energy is changing most rapidly with changes in transition temperature.

The transition temperature values for the two steels are plotted as a function of ferrite grain size in Fig 18. A straight line relationship between ferrite grain size and transition temperature for each of the steels is indicated by these results. An increase of ferrite grain size of one A.S.T.M. grain size number is thus seen to raise the transition temperature by 30°F in each steel. The transition temperature of the 3.64 pct nickel steel is, however, 60°F lower at a given ferrite grain size than the plain carbon steel, even though the nickel steels are at a somewhat higher hardness level. Inasmuch as the other variables were held constant, this improvement in notch toughness, represented by the lower transition temperatures of the nickel steels, is apparently a specific effect of nickel as an alloying element in ferrite.

The average impact values at room temperature for both steels are plotted as a function of ferrite grain size in Fig 19. A fair correlation also exists between these room temperature values and ferrite grain size, an increase in ferrite grain size of one A.S.T.M. grain size number decreasing the impact value by approximately 8 ft-lb. This relationship, however, appears to be independent of nickel content, as the nickel steel does not show consistently higher impact values than the plain carbon steel at a given grain size level.

FACTORS GOVERNING FERRITE GRAIN SIZE

The range of ferrite grain sizes studied in this investigation was obtained by varying both the austenitizing temperature and the cooling rate. The relationships among austenitizing temperature, cooling rate and ferrite grain size for the steels of this investigation are summarized in Fig 20. It was found that, at a constant cooling rate, the ferrite grain size changed rather slowly with changes in austenitizing temperature, an increase in austenitizing temperature from 1800 to 2000°F corresponding to an increase in ferrite grain size of about one grain size number. Increasing the cooling rate, however,

was much more effective in decreasing the ferrite grain size of the plain carbon steel than that of the nickel steel. Increasing the cooling rate from a furnace cool at 20°F per hr to a brine quench, decreased the ferrite grain size of the plain carbon steels by approximately two grain size numbers, while a similar change in cooling rate resulted in a decrease of only one grain size number for the nickel steel.

The effect of cooling rate on the ferrite grain size in the two steels was further evaluated by end quench tests. One-half inch diameter specimens were used because of the size limitation, and the standard procedure for ½ in. end quench tests was followed. The specimens of both steels were austenitized

at 1700°F, and the results are plotted in Fig 21 in terms of ferrite grain size as a function of distance from the quenched end. Here again, the plain carbon steel shows a much more pronounced effect of cooling rate on ferrite grain size than does the nickel steel.

The above results are explainable on the basis that the ferrite grain size for a given austenite grain size reflects the average temperature at which ferrite precipitates during cooling. The slower transformation rate of the nickel ferrite would thus result in a lower average temperature of ferrite precipitation at a given cooling rate and a correspondingly smaller, final ferrite grain size. Furthermore, the differences in the effect of cooling rate on ferrite grain

size would be expected to be larger at the slower cooling rates inasmuch as the differences in transformation rates to ferrite between nickel and plain carbon steels are generally more pronounced at the higher transformation temperatures.

Conclusions

1. The keyhole notch Charpy transition temperature of 0.02 pct carbon steels is a straight line function of the ferrite grain size, the transition temperature being raised 30°F by an increase in ferrite grain size of one A.S.T.M. grain size number.

2. The keyhole notch Charpy transition temperature is lowered 60°F at a constant ferrite grain size in 0.02 pct carbon steels by alloying with 3.64 pct nickel.

3. The room temperature impact value in the keyhole Charpy impact test for each steel is also a function of the ferrite grain size, increasing as the grain size decreases.

4. At a given ferrite grain size, the room temperature impact value in the keyhole Charpy impact test is unaffected by alloying with 3.64 pct nickel.

Effect of Recrystallization Texture on Grain Growth

By PAUL A. BECK,* Member AIME, and PHILIP R. SPERRY*

It has been shown¹ that in polycrystalline strips of high purity aluminum with a fairly random orientation distribution, grain growth progresses gradually until the average grain diameter reaches a value approximately equal to the strip thickness. Recent work at this laboratory led to the realization that grain growth might be impeded to a considerable extent in the presence of a sharply defined texture, where orientation differences between neighboring grains are small.

In order to investigate this effect the following experiment was carried out with the same lot of high purity aluminum previously used for grain growth studies in randomly oriented material.¹ Very large grain size was

developed by grain growth at 650°C in specimens of 0.200 in. thickness. These specimens were then rolled to a thickness of 0.050 in. or 1.25 mm—a reduction of 75 pct. In the rolled strip each large grain corresponded to an elongated area easily identified by etching. After annealing for 1 to 25 min at 600°C and re-etching, these elongated areas were again recognizable. Within each area, corresponding to a single

large grain before annealing, there formed by recrystallization a multitude of new grains with a fairly well developed preferred orientation. The orientation and the size of the new grains formed in areas corresponding to different large grains, varied widely depending on the orientation of the parent grains with respect to the rolling direction and the plane of rolling. Many areas were found where the average grain size was considerably smaller than the specimen thickness. Such an area occurred in a specimen cut in half before annealing. One half, containing a portion of the area in question, was annealed 1 min at 600°C, the other half, with the remaining portion of this area, for 25 min at the same tempera-

ture. It was apparent that the annealing time had very little effect on the size of the small grains produced by recrystallization from a single large grain of the original rolled specimen. They possessed a very well developed preferred orientation, which made it somewhat difficult to detect the grain boundaries for accurate grain size determination. However, after some experimentation, it was found possible to make fairly accurate determinations. These are presented in the Table 1, which also includes for comparison the grain sizes obtained by similar anneals in specimens from the same bar of aluminum, rolled to the same final thickness, but exhibiting little preferred orientation (penultimate condition: fine grained, polycrystalline; last reduction: 33 pct).

Table 1 . . . Effect of Annealing Time and Orientation on Grain Size

| Annealing Conditions | Average Grain Size, mm | |
|----------------------|------------------------------|--------------------|
| | Strong Preferred Orientation | Random Orientation |
| 1 min at 600°C..... | 0.33 | 0.61 |
| 25 min at 600°C.... | 0.36 | 1.0 |

The fact that with a strong texture the grain size remained practically constant from 1 to 25 min at 600°C, at a value much smaller than the specimen thickness, proves that in a highly oriented aggregate of crystals, grain growth is greatly reduced, if not entirely impeded. It is quite possible that this reluctance of grains to grow, even though they are small, when their orientations are very nearly the same, is a result of the low surface tension values associated with grain boundaries under such conditions.²

The close connection between a certain type of coarsening and the inhibition of gradual grain growth by a dispersed second phase has been known for a long time.³ These relationships were recently explored in a quantitative and rather detailed manner.⁴ However, from the results of Dahl and Pawlek⁵ and of Cook and Macquarie⁶ it may be concluded^{4,7} that in certain metals coarsening may also occur *without* a dispersed second phase, provided that the conditions of penultimate grain

FIG 1—Partially coarsened tough pitch copper specimen, cold rolled 90 pct, annealed 3 min. at 1000°C. Magnification 5 ×. (Reduction approximately one-half.)

size, of amount of reduction by rolling, and of composition are such that a strongly developed cube texture results upon recrystallization. This texture, in which the fine recrystallized grains have very closely identical orientation, appears to resist gradual grain growth up to relatively high temperatures. In copper with the cube recrystallization texture, extremely coarse grains abruptly develop when the temperature is raised to approximately 1000°C (see Fig 1). These very large grains have a fairly well developed preferred orientation of their own,^{5,8} different from that of the fine grained recrystallized matrix in which they grow. This fact may be interpreted as an indication that in a highly oriented fine grained matrix, the rate of growth of a grain strongly depends on its orientation with respect to the preferred orientation of the matrix. The alternative interpretation, namely, that the preferred orientation of the coarse grains is a result of the presence in the matrix of "nuclei" of a certain orientation only⁸ appears less convincing. It seems justified to assume that "texture-dependent coarsening" is intimately connected with the above described restraint of gradual grain growth by virtue of a strongly developed texture, just as "inhibition-dependent coarsening" is connected with grain growth inhibition by a dispersed second phase.

Recrystallization and Microstructure of Aluminum Killed Deep Drawing Steel

R. L. RICKETT,* Member, S. H. KALIN,† and J. T. MACKENZIE, JR.,‡ Junior Member AIME

ALUMINUM killed low carbon steel,§ which is now used extensively for severe deep drawing or other difficult forming operations, is unusual in that its grain structure, after cold reduction and box annealing in accordance with conventional continuous sheet or strip mill practice, often is elongated, although at times it is equiaxed. Since this unusual structure has been found superior for many, but not all, severe forming operations, recrystallization of the steel, both at constant temperature and on continuous heating, was investigated and compared with that of rimmed steel in the hope that something might be learned about the mechanism of, and the factors controlling, the formation of such elongated grains.

In this structure, the grains are elongated both in the lengthwise direction of the strip and transverse to this direction, even though nearly all of the extension in both hot and cold rolling is in the lengthwise direction. The grains are thus roughly pancake-shaped, being longer and wider than they are thick, as observed also by Burns and McCabe,¹ and as illustrated by the typical structures shown in Fig 1. Fig 1a, representing a conventional longitudinal section, shows the length and thickness of the grains, whereas Fig 1b shows their length and width as seen by examining a section parallel to the sheet surface. Both illustrate the very irregular grain boundaries usually associated with the elongated grain shape. A finer equiaxed grain structure in this same grade is shown in Fig 1c. Either the elongated or the equiaxed structure may be present in the annealed product, and in rare instances the two types may coexist in a single specimen, as shown in Fig 1d.

Isothermal Recrystallization of Rimmed and Aluminum Killed Steel

An aluminum killed steel known to have an elongated grain structure after conventional processing (Steel B, Table 1), was selected for the initial recrystallization studies; for comparison, a rimmed steel, A in Table 1, was used. Samples of each in the form of hot rolled strip 0.075 and 0.095 in. thick, respectively, were cold rolled on a small laboratory mill in steps of about 0.010 in. per pass to obtain total reductions

of 40 and 60 pct. Small pieces of the cold reduced strip were heated in lead at selected constant temperatures for one of several periods of time, then cooled in air. Rate of heating in the lead was, of course, very fast. Hardness of the cooled specimen was measured and a longitudinal section examined metallographically.

Isothermal recrystallization curves for these two steels at 1050°F, based on hardness of the air cooled specimens, are shown in Fig 2 in which the amount of recrystallization corresponding to each plotted point is indicated. The marked difference in the behavior of these two types of steel is evident. After a corresponding amount of cold reduction, the rimmed steel recrystallizes in a much shorter time than the killed steel and the shape of its recrystallization curve, (plotted on a logarithmic time scale), is very different. The curve for rimmed steel indicates that recrystallization is analogous to isothermal transformation of austenite in that it proceeds at a progressively faster rate up to some 50 pct recrystallization, then at an increasingly slower rate. For the aluminum killed steel, however, the start of

recrystallization is followed by a period during which little further change occurs, after which recrystallization of the remaining cold worked metal proceeds at a relatively fast rate. The hardness curve thus exhibits an initial gradual drop, then a nearly horizontal portion or "shelf" and finally a rather sharp drop. The "shelf" is lowered by increased cold reduction and, as discussed later, by increased temperature.

These two types of steel also differ considerably in microstructure both during and after recrystallization, as shown in Fig 3 and 4. In rimmed steel, Fig 3, the first recrystallized grains are nearly equiaxed, and remain so as they grow and new grains continue to form. In the aluminum killed steel however, Fig 4, the small new grains, which may be equiaxed as first formed, become elongated as they grow, apparently because resistance to growth in the thickness direction of the sheet is greater than in the lengthwise or crosswise direction. Both rate of growth and rate of formation of new grains (nucleation) are much less in the aluminum killed than in the rimmed steel.

Grain growth restraint in the aluminum killed steel appears to be greatest at boundaries of the cold worked grains, as illustrated in Fig 5. Even in the rimmed steel, Fig 5a and 5b, there is some tendency for grain growth to stop at former grain boundaries but this tendency is much more marked in the killed steel, Fig 5c and 5d. This grain boundary restraint, together with the relatively slow rate of nucleation in this type of killed steel, apparently is responsible for its relatively coarse elongated grain structure after recrystallization. The presence of thorium oxide particles, similarly, has been shown to restrain grain growth and result in an elongated grain structure in recrystallized tungsten wire.^{2,3} It still is not clear, however, why grain growth of aluminum killed steel is restrained more effectively in the thickness direction than it is in the lengthwise or crosswise direction of the sheet, as it must be if such restraint is responsible for the plate-like shape of the recrystallized grains. This effect suggests the possible presence in the steel of fine particles distributed more or less in layers parallel to the sheet surface.

As expected, increased cold reduction reduces the time required for complete recrystallization of either of the steels represented in Fig 2 and increases their hardness as fully recrystallized. This

FIG 1—Types of microstructure observed in aluminum killed steel after cold reduction and box annealing. 100 \times . Nital etch.

increased hardness is due to a finer grain size, as illustrated in Fig 6. For the same amount of prior cold reduction the killed steel, with its elongated grain structure, is softer, and its grain size coarser, than the equiaxed rimmed steel.

Effect of Temperature of Isothermal Recrystallization

The effect of temperature on rate of isothermal recrystallization was investigated, again using rimmed steel A and killed steel B of Table 1, each cold reduced 40 pct. For rimmed steel, Fig 7a, the shape of the recrystallization curve is not altered appreciably by change in temperature, although as would be expected the time required for a comparable amount of recrystalli-

zation is less the higher the temperature. Fig 7a shows that over the range 1000 to 1100°F, hardness of this steel after complete recrystallization is nearly independent of recrystallization temperature; final grain size, likewise, was found to be about the same for all.

The effect of temperature, in the range 1050 to 1200°F, on isothermal recrystallization of the aluminum killed steel is shown in Fig 7b. At each temperature investigated, the amount of recrystallization remains nearly constant over an appreciable period of time, resulting in a "shelf" in the recrystallization curve. The amount of recrystallization corresponding to this shelf increases, and the time to attain it decreases, with increased temperature. Duration of the shelf period also is shorter the higher the temperature. Hardness of this steel as fully recrystallized increases as the recrystalliza-

FIG 2—Rate of isothermal recrystallization of rimmed steel A and aluminum killed steel B at 1050°F after 40 pct and after 60 pct cold reduction.

tion temperature is raised, Fig 7b, the higher hardness resulting from a finer, more equiaxed grain structure, as shown in Fig 8.

The aluminum killed grade thus differs from rimmed steel in requiring a longer time for complete recrystallization at comparable temperature, in having a “shelf” in its isothermal recrystallization curve, and in becoming finer grained as the recrystallization temperature is raised.

Effect of Treatment Prior to Cold Reduction

Early in this investigation, it was discovered that normalizing the aluminum killed steel at about 1700°F after hot rolling, but before cold reduction, resulted in an equiaxed rather than an elongated grain structure after subsequent cold reduction and box annealing. This observation led to a more extensive study of the influence of such heating prior to cold reduction on final grain structure.

Specimens of steel B of Table 1, in the form of hot rolled strip 0.075 in. thick, were heated at each of a series of temperatures for 20 min. then air cooled. Another set was prepared in which the heating time was 2 hr. The specimens of both sets were then cold reduced 40 pct in thickness, using a small laboratory rolling mill, after which they were annealed 16 hr at 1275°F in a protective atmosphere. The laboratory annealing cycle simulated commercial box annealing practice, both heating and cooling rates being in the range of 20–50°F per hour. Microstructure, after cold reduction and annealing, of the specimens heated

for 20 min. or 2 hr prior to cold reduction is shown in Fig 9. Holding 2 hr at 1000°F had little effect on the final structure, but 2 hr at 1100°F resulted in a mixed elongated and equiaxed structure, whereas holding

2 hr at 1200°F or above resulted in a final structure that is almost entirely equiaxed.

The change in grain structure, as box annealed, from elongated to equiaxed is accompanied by an appreciable increase in hardness of the annealed material. Fig 10 shows the relationship between temperature of heating, prior to cold reduction, and hardness of the subsequently cold reduced and box annealed product. The two curves in Fig 10 are for 20 min. and 2 hr at temperature in the initial treatment, and show that the longer time lowers the temperature range over which the change in final structure and hardness takes place. Fig 11 shows that prior heating for as long as 24 hr at 800 or 1000°F had no appreciable effect on final hardness whereas 2 hr at 1200°F or 5–10 min. at 1300°F increased hardness of the cold-rolled, annealed material to a maximum; this maximum hardness corresponds to a substantially equiaxed grain structure. Fig 10 and 11 thus demonstrate that the change in

FIG 3—Progress of isothermal recrystallization of rimmed steel A at 1050°F after 60 pct cold reduction. 500 ×. Nital etch.
a. 2 min. b. 4 min. c. 8 min. d. 12 min.

structure and hardness as annealed is dependent upon both time and temperature of the treatment prior to cold reduction, the time required being shorter the higher the temperature, within the range investigated.

The foregoing observations indicate that slow rather than rapid cooling of this aluminum killed steel directly following hot rolling should yield an equiaxed grain structure after subsequent cold reduction and annealing. This was confirmed by cooling samples at three rates after heating to 2150°F and hot rolling from 0.15 to 0.085 in. (43 pct reduction) in a single pass through a small laboratory rolling mill. The three rates of cooling were obtained by: (1) quenching in oil, (2) cooling in air, and (3) placing in a furnace at 1500°F immediately after hot rolling and cooling with the furnace (1 hr to cool from 1500 to 1350°F). After cold rolling 40 pct and box annealing 16 hr at 1275°F, grain structure of the previously oil quenched or air

cooled samples was elongated, whereas that of the slow-cooled sample was equiaxed, as shown in Fig 12.

The foregoing experiments demonstrate that the thermal history between hot rolling and cold reduction is an important factor in determining whether the grain structure of this aluminum killed steel, when recrystallized after cold reduction, will be elongated or equiaxed. Either slow cooling from the temperature at which hot rolling is finished, or suitably reheating more rapidly-cooled strip leads to the formation of equiaxed grains in the final annealed product similar to those commonly found in box annealed rimmed steel. This raised the question whether the recrystallization of "equiaxed" aluminum killed steel may not also resemble that of rimmed steel, rather than being much more sluggish as is characteristic of the elongated-grain type (Fig 2 and 7). To answer this question, suitable samples cold rolled 40 pct were recrystallized isothermally

at 1050°F, with results shown in Fig 13 and 14.

To determine the effect of cooling rate on isothermal recrystallization at 1050°F, Fig 13, specimens of steel D, Table 1, were hot rolled in regular production, and cooled rapidly to about 1330°F; a portion was then cooled slowly below this temperature, whereas another portion was cooled much more rapidly. The rapidly cooled portion, subsequently cold rolled and completely recrystallized at 1050°F, had an elongated grain structure, and, as shown in Fig 13, its recrystallization curve exhibits the "shelf" characteristic of such material. The more slowly cooled strip when cold reduced and recrystallized had an equiaxed grain structure like that of rimmed steel; the recrystallization curves for this and for the rimmed steel in Fig 13 likewise are similar in shape, although the killed steel recrystallized somewhat more slowly. Fig 14 shows the effect of reheating to 1300°F after hot rolling on isothermal recrystallization after cold reduction, the steel being the same aluminum killed steel as in Fig 2. The effect of this treatment on recrystallization is the same as that of slowly cooling the strip directly after hot rolling; recrystallization proceeds more rapidly, and in more continuous fashion than when the strip is cooled rapidly after hot rolling and is not reheated. Final recrystallized grain structure of this steel previously heated at 1300°F before cold reduction was equiaxed, whereas without such treatment it was elongated.

Fig 13 and 14 thus demonstrate that when the treatment of aluminum killed steel prior to cold reduction is such that the final recrystallized grain structure is equiaxed rather than elongated it recrystallizes more readily and its recrystallization curve exhibits no "shelf," thus resembling rimmed steel in these respects.

Recrystallization on Continuous Heating

In regular commercial practice cold rolled strip or sheet is box annealed in the approximate temperature range 1200–1350°F after cold reduction. Rate of heating is necessarily rather slow, because a large amount of metal is annealed in each batch, and partial or complete recrystallization occurs during the heating period. Since the structure of aluminum killed deep drawing

FIG 4—Progress of isothermal recrystallization of aluminum killed steel B at 1050°F after 60 pct cold reduction. 500 X. Nital etch.

sheet varies with the temperature at which it is recrystallized (Fig 8) it was decided to investigate the recrystallization of this steel on continuous heating at several rates, and the effect of such variation in heating rate on the final grain structure.

For this purpose, Steels *E*, *F*, *G*, and *H* of Table 1 were used; *E* was cold reduced 40 pct in the laboratory, the others were cold rolled in regular production. Several specimens of each were heated at a controlled constant rate of 20, 50, or 300°F per hr in lead, starting at 700°F. As each selected temperature was reached, a specimen was removed from the lead and air cooled.

Results of these tests for Steels *F*, *G* and *H* are shown in Fig 15. When heated continuously at 20°F per hr, Fig 15a, steel *F* started to recrystallize at about 1050°F but had not recrystallized completely on reaching 1150°F, the highest temperature investigated. The hardness curve for Steel *G* follows closely that for Steel *F*; however, *G* was completely recrystallized on reaching 1100°F. Steel *H* differs from the others in that it recrystallized over a considerably lower temperature range. Structure of all three steels after recrystallization was elongated.

As would be expected, the effect of increasing the heating rate, Fig 15b and 15c, is to raise the recrystallization temperature range. The curve for Steel *G* heated at 300°F per hr exhibits a "shelf" not apparent at slower heating rates; the curve for Steel *H* also has a

“shelf” at somewhat lower hardness. This latter steel is unusual in that its recrystallized grain structure becomes much finer and more nearly equiaxed when the rate of heating is raised from 50 to 300°F per hr. No such effect was found in the other steels over the range of heating rate investigated.

Differences among these steels do not seem to be related to their composition, as given in Table 1, but are believed to be due to differences in prior processing, as discussed below, although this is not known with certainty.

Recrystallization on continuous heating, like isothermal recrystallization, is influenced by treatment of the steel prior to cold reduction. Fig 16 shows the effect of heating Steel E, Table 1, 20 min. at 1300°F before cold rolling as compared to the same steel hot rolled only before cold reduction. The 1300°F treatment prior to cold reduction lowers the recrystallization temperature range for each of the three heating rates and results in an equiaxed rather than an elongated recrystallized grain structure. From this, it appears likely that Steel H, Fig 15, was cooled after hot rolling in such a man-

ner that its tendency toward an elongated grain structure, on recrystallization, was only partly destroyed rather than completely destroyed as was that of Steel E when heated to 1300°F after hot rolling.

Summary

The results of this investigation show that the recrystallization of rimmed steel at constant temperature proceeds in a regular and continuous manner, once it starts, as is already well known. On the other hand, the recrystallization of aluminum killed steel of the elongated-grain type takes place in three rather distinct stages: (1) an initial period resembling the start of recrystallization in rimmed steel; (2) a second period during which recrystallization proceeds very slowly; and (3), comparatively rapid recrystallization of the remaining unrecrystallized portion. The length of time required for complete recrystallization is ordinarily much greater for the aluminum killed steel than for rimmed steel at a comparable temperature. Except at the very start, the recrystallized grains in this type of killed steel are definitely elongated

whereas the grains in rimmed steel are predominantly equiaxed.

An increase in temperature accelerates the recrystallization of rimmed steel but does not essentially change the *shape* of the isothermal recrystallization curve; final grain size and hardness are changed to a minor extent, if at all. In the isothermal recrystallization of aluminum killed steel, increase in temperature increases the amount of recrystallization which takes place in the initial stage, shortens the second and third stages but does not eliminate them, and makes the grain size finer and more nearly equiaxed.

The isothermal recrystallization pattern of subsequently cold reduced aluminum killed sheet steel may be made to approach that of rimmed steel by slowly cooling the hot rolled strip or by reheating it for a sufficient length of time to a temperature of approximately 1200°F or above, then cooling at any convenient rate; the recrystallized grain size is then comparatively fine and the grains tend to be equiaxed.

The recrystallization temperature range on continuous heating of aluminum killed steel is raised by increasing the rate of heating and in some instances the grain structure becomes finer and more equiaxed. Treatments prior to cold reduction that result in an equiaxed structure on subsequent recrystallization lower the recrystallization temperature range on continu-

ous heating.

It was observed that when killed steel recrystallizes to an elongated-grain structure the first new grains to form are widely scattered and initially may be more or less equiaxed; as they grow they have considerable difficulty in crossing the cold-worked grain boundaries and consequently become elongated in shape like the original deformed grains. Recrystallization gradually progresses to adjacent cold-worked grains so that the final recrystallized grains are, to some extent, built up of elongated units which correspond to the original deformed grains. When recrystallization takes place at a comparatively low temperature, the number of locations or nuclei where new grains start is limited and the final grain size is coarse; but as the recrystallization temperature is increased, more nuclei form, the final grain size becomes finer, and the grains tend to be less elongated. In rimmed steel, or in killed steel which recrystallizes to give an equiaxed structure, the number of nuclei increases rapidly as recrystallization progresses and becomes much greater than in killed steel of the elongated-grain type at the same temperature; resistance to growth across the old grain boundaries is also less; the result is an equiaxed grain structure and, generally, a finer grain size. The formation of coarse, elongated, recrystallized grains appears, therefore, to

be due to some factor which reduces the number of effective recrystallization nuclei and also restrains grain growth. The precise nature of this restraining influence has not been established.

Acknowledgments

This investigation was suggested by Dr. John Johnston, then Director of Research, United States Steel Corporation. The assistance of various operating personnel, particularly at Gary Sheet and Tin Mill and Irwin Works of Carnegie Illinois Steel Corporation, in supplying materials and that of Gary Works Laboratory in making the hot rolling tests is greatly appreciated, as are the suggestions of associates in both the Research Laboratory and operating companies. Messrs. H. M. Evers and L. B. Haberman helped with portions of the experimental work.

Precipitation Phenomena in the Solid Solutions of Nitrogen and Carbon in Alpha Iron below the Eutectoid Temperature*

L. J. DIJKSTRA†

Introduction

DURING the past several years an extensive study has been made of the internal friction of iron containing carbon or nitrogen in solid solution.^{1, 2, 3, 4, 5} It has been found that a sharp peak is observed in a plot of the internal friction vs. temperature of measurement. With a frequency of about one cycle per second, this peak occurs at 20°C for N and 36°C for C. The physical origin of this anomalous internal friction was traced by Snoek¹ to the local tetragonal symmetry of the interstitial positions in body centered cubic (bcc) iron. A change in stress induces a change in the equilibrium distribution of the interstitial atoms among the three types of interstitial positions, the three types corresponding to the three directions along which the tetragonal axis may lie. It is the continual striving of the interstitial atoms to maintain an equilibrium distribution that gives rise to a phase lag between strain and stress during oscillation, and hence, to internal friction. A similar type of internal friction has been observed in the bcc lattice of tantalum containing in interstitial solid solution C, N or O⁶.

The theory of this anomalous internal friction leads to the prediction that its magnitude is strictly proportional to the concentration of either the carbon or the nitrogen in solid solution, provided the concentrations are small. This prediction has been verified³ for the range of solubilities obtainable in alpha iron. This proportionality provides us with a new tool for the study of nitrogen and carbon in alpha iron. It thus enables one directly to follow the precipitation of either of these solute atoms from solid solution and also directly to measure their solubility as a function of temperature. A

FIG 1—(Above) Fe-N equilibrium diagram (after Lehrer-Eisenhut and Kaupp²).

preliminary study of precipitation using this method has already been presented by the author.³ The purpose of this paper is to present more extensive observations upon the precipitation of N and C in alpha iron, as well as to present observations upon the solubility of N and C in alpha iron which, at least in the lower tempera-

ture range, are believed more accurate than those previously obtained by other methods.

The interpretation of the observations upon precipitation involves the use of the appropriate equilibrium diagrams. For ease of future reference in this paper the equilibrium diagrams for the Fe-N and Fe-C systems are accordingly reproduced as Fig 1 and 2, respectively.

Experimental Procedure

The specimens were made of Westinghouse Puron iron and consisted of wires 0.025 in. in diam and about 1 ft long. By a wet hydrogen treatment the specimens were purified of C and N. In

FIG 2—(Below) Fe-C equilibrium diagram.

order to make internal friction measurements the wires were used as the suspension element in a torsional pendulum system with a period of vibration of about 1 sec. The damping is determined by measuring the logarithmic decrement of the free torsional vibration using a very small vibrational amplitude. The apparatus is very similar to that previously described by T. S. Kê.⁴ The wire was surrounded by a furnace to enable us to vary the temperature, which variation is necessary in locating the maximum in the internal friction. All data have been corrected for a relatively small background damping of $Q^{-1} = 0.001$. Here, as in the following, we shall take as the quantitative measure of internal friction the quantity Q^{-1} , which is $\frac{1}{2}\pi$ times the logarithmic decrement, $(\frac{1}{2}\pi)$ times the specific damping capacity. A calibration of the value of Q^{-1} at the maximum of the internal friction peak, Q_{max}^{-1} , vs. resistivity, and a comparison of Köster's⁷ resistivity vs. concentration curves, has shown that Q_{max}^{-1} is equal, within the 10 pct accuracy of the measurements, to the wt pct concentration in the case of both carbon and nitrogen in solid solution.

The N was introduced in the standard way by annealing the specimen in a mixture of H₂ and 3-5 pct (by volume) of NH₃ at 580° for some hours, until the wire was homogeneously

loaded with N. The homogeneous distribution throughout the specimens could be checked microscopically after precipitation. By varying the partial pressure of the NH₃ in the mixture the amount of N introduced could be controlled. After quenching from 580°C by immersion into cold water or by exposure to a compressed air stream all the N was retained in supersaturated solid solution, as was verified by varying the quenching rate.

The C was introduced in a similar way by annealing the sample at 700°C in a mixture of H₂ and benzene, followed by quenching in cold water.

The introduction of N and C by this method has the disadvantage that atomic H is generated which will readily enter into the Fe-lattice. It is well known that the absorption of H affects the mechanical properties of Fe. Most of the H will diffuse out again by heating in a neutral atmosphere. Iron which was pickled in acid, and which had thereby taken up a large amount of H, did not show any contribution by H to the internal friction in the temperature region between -40 and 100°C. How far the specimen may have been damaged by the H, for example, by causing small rifts and thus affecting the precipitation phenomena, we do not know, but assume it is not serious.

The general procedure was as follows. After being quenched from the

nitriding or carburizing temperature to room temperature, the specimens were tempered at a definite temperature. In order to determine the C or N content still present in solid solution after increasing periods of tempering, the specimens had to be quenched to room temperature to measure Q_{max}^{-1} , which took about 5 min. The drop in Q_{max}^{-1} due to aging during this short interval was generally negligible. Sometimes the time intervals of tempering were rather short (15 sec), necessitating rapid heating to the tempering temperature. For this purpose hydrogen was used as the tempering atmosphere at moderate temperatures (heating time was 3 sec in H₂, 30 sec in air). At temperatures above 400°C we used He since the N and C content of the wire decreased noticeably at these temperatures in a hydrogen atmosphere.

It was found possible to use a single specimen in a whole series of measurements. After aging or tempering, during which the N or C had been rejected partially or completely from solid solution, the original state of complete solid solution was reestablished by what we shall call a re-solution heat treatment. This re-solution heat treatment consisted of a 580°C (or 720°C for C) anneal for about 1 sec and subsequent quenching. This was repeated more than 50 times without any change being noticed in the initial value of

FIG 3—Typical room temperature aging curves; 1,2,3,4 as quenched; 4a same as 4, except for cold work following quench.

Q_{max}^{-1} . Even after extended tempering times at higher temperatures no more than 5 sec were required to eliminate the tempering effects. After this re-solution heat treatment one could start again and find the measurements reproduced quite satisfactorily.

Internal Friction Measurements

We first confine ourselves to the case of nitrogen in solid solution. A brief discussion of carbon in solid solution will be given at the end of this section.

Fig 3 shows typical aging curves for four specimens. They were all slowly cooled from 950°C and afterwards loaded with different amounts of N as indicated by the initial Q_{max}^{-1} . After a re-solution heat treatment specimen 4 has been cold worked to 48 pct reduction in area. The corresponding aging-curve is denoted as 4a. These curves show clearly the large influence of the initial concentration of N and of the state of cold work upon the rate at which N is rejected from solid solution. To investigate the effect of temperature these two factors should be kept constant; this was assured by the re-solution heat treatment.

In Fig 4a and 4b are reproduced a typical set of tempering curves for a series of temperatures ranging from 0 to

500°C. The curves for the temperatures 250, 275, and 300°C are only partially drawn in Fig 4a; the complete tempering curves are given in Fig 4b. All the measurements were made on the same specimen, which, before nitriding, had been slowly cooled from 950°C. The various measured initial values of Q_{max}^{-1} , of about 0.042, corresponding to a total N content of about 0.04 pct, show how nicely they are reproduced by the re-solution treatment. The time scale is a logarithmic one. We wish to point out the following:

1. If a linear time scale is used instead of a logarithmic one, a number of curves, especially those for the lower temperatures, still show the very small initial slope which rapidly increases. This may mean that some nucleation stage is involved, usually called incubation or induction period.

2. After the initial drop (*dash*) the curves approach a horizontal section. This indicates that a stationary state, which can be temporary, is approached in which the N concentration in solid solution has decreased to a certain constant value. This residual value is zero within the limits of measurements, at temperatures below 100°C, but increases rapidly for higher temperatures.

3. For more extended tempering times at intermediate temperatures a second drop (*solid line*) starts and continues until a final equilibrium state is

reached, which final state proved to be permanent even for very extended tempering times. The tempering times for temperatures below 250°C have been too short to observe the second drop, though there can hardly be any doubt that it must also be present below this temperature.

At temperatures above 250°C there seems to be no opportunity for the intermediate, "stationary" state to develop completely, due to the interference with the second drop. Above 300°C the first drop has completely disappeared and only the second process remains. The final residual solubility rapidly increases with temperature and at 500°C no decrease of Q_{max}^{-1} on tempering could be observed for this N content.

4. If we further compare the dashed tempering curves for different temperatures in Fig 4a, then we see there is a shift to the left with increasing temperature. This shift is almost parallel as long as the curves drop to a low value. Above 250°C this shift to the left reverses into a shift to the right, towards longer tempering times. The solid curves show about the same behavior.

Considering the dashed curves, we shall define a half time value $t_{1/2}$ as being the time necessary to reach the Q_{max}^{-1} midway between the initial and residual value. In Fig 5 $\log t_{1/2}$ has been plotted against $1/T$ in the region 0 to 200°C. The dots and circles refer to two different successive runs through the whole temperature region. The curves seem rather straight, but show a somewhat sudden bend at 100 and just below 20°C. This bend was reproducible and seems to indicate that the phenomenon is rather complicated.

5. The specimen was then annealed for $\frac{1}{2}$ hr in wet H_2 at 700°C and afterwards for some hours in dry H_2 at 500°C to assure a homogeneous distribution of the N. After this treatment the Q_{max}^{-1} was 0.023, corresponding to a total N content of about 0.02 pct. The tempering curves for this concentration in Fig 6 show the same general behavior as those in Fig 4. The dashed curves, as well as the solid one, seem to approach the same equilibrium values of Q_{max}^{-1} as the curves in Fig 4. (The Q_{max}^{-1} scale is different in Fig 4 and 6.) The only obvious effects of the concentration difference are, first, a large increase in $t_{1/2}$ below 100°C so that the sudden bend in the curve at 100°C in Fig 5 has disappeared, and secondly, a lowering of the temperature at which

FIG 4a—Effect of aging at low temperatures ($R.T.$ — 300°C). All measurements are at room temperatures following indicated aging. Initial concentration of nitrogen is 0.043 wt. pct.

FIG 4b—Effect of aging at high temperatures (250 – 500°C). Dashed lines: intermediate precipitation. Full lines: precipitation of Fe_4N .

the first drop disappears. The solid curves for 250°C in Fig 4b and 6 are almost identical, although in Fig 4b a large first drop has preceded it.

We may briefly summarize the above observations as follows: At intermediate temperatures the rejection of N from the supersaturated solid solution takes place according to two different successive processes. By lowering the temperature the earlier reaction will predominate; by raising the temperature, the later one. The fact that the completion of the earlier rejection process does not seem a necessary condition for the beginning of the second one (in a certain temperature region we even observe that the temperature dependence of the rate of both

processes has a different sign), suggests that the two processes occur independently of each other with rates having a different temperature dependence.

It seems most natural to relate each quasi-stationary or stationary state in the tempering curves to the existence of some Fe-N phase, whatever it may be. The height of a horizontal part represents the solubility of N in α -iron in equilibrium with the corresponding Fe-N phase. According to the preceding paragraph, it appears, then, that the observed Fe-N phases are independent of one another, that the earlier phase is not an intermediate or transitional state of the final phase.

In the case of a perfect solid solution

the solubility $[c]_{\text{sat}}$ must satisfy a relation of the type

$$\left(\frac{\partial \ln [c]_{\text{sat}}}{\partial T}\right)_p = \frac{\Delta H}{RT^2}$$

or

$$\ln [c]_{\text{sat}} = -\frac{\Delta H}{RT} + \text{const.}$$

ΔH is the heat of solution per gram mol. of the precipitated phase. In Fig 9 the values of $[c]_{\text{sat}}$ as given by the horizontal parts in Fig 4, and in a number of curves which we did not reproduce, have been plotted on a logarithmic scale versus $\frac{1}{T}$ both for the intermediate phase (curve 1) and for the final phase (curve 2), which we assume to be Fe_4N . The values

FIG 5—Temperature dependence of time required for precipitation to be one-half complete for two initial concentrations.

FIG 6—Effect of aging at low temperatures (*R.T.*—300°C). All measurements are at room temperatures following indicated aging. Comparison with Fig 4*a* illustrates effect of initial concentration upon rate of precipitation.

for Fe_4N from Fig 4a for the lower temperature are probably too high because the tempering times have been too short to reach real equilibrium. At the highest temperatures we met with the difficulty that the N content seemed to decrease during tempering, even using He as a gas atmosphere. Therefore we followed another way and nitrided the specimen at 575°C for a sufficiently long time in $\text{H}_2 + \text{NH}_3$ mixtures of increasing NH_3 content until no further increase in Q_{max}^{-1} was observed. This final value of Q_{max}^{-1} gives us the solubility for Fe_4N at 575°C . It would take us too long to do the same for all the lower temperatures. Therefore we simply annealed this loaded specimen at the desired lower temperatures in adequately rich $\text{H}_2 + \text{NH}_3$ mixtures, during which Q_{max}^{-1} dropped until the equilibrium value was reached. These values are given by the black dots in Fig 9 and seem to us to be the best ones. From the slope of the curve we calculate that ΔH for both precipitates is of the order of 8,000 cal per mol. An extrapolation of our data to 590°C , the eutectoid temperature for the Fe-N system, gives for the maximum solubility about 0.10 pct.

It is possible to get higher concentrations of N into solid solution in the following way: by annealing in $\text{H}_2 + \text{NH}_3$ mixtures above the eutectoid temperature some f.c.c. γ -phase is formed (see Fig 1) which by rapid quenching down to room temperatures apparently transforms into the bcc α -phase. During this quenching no precipitation takes place, though there must have been some diffusion of N between adjacent interstices in order to obtain the cubic phase and not a martensitic structure. In this way we have observed values for Q_{max}^{-1} of 0.12. These highly supersaturate solutions are extremely unstable and precipitate at room temperature in about 5 min.

The precipitation of C from a supersaturated solid solution has been investigated along lines similar to that for N. The value of Q_{max}^{-1} in the freshly quenched state was 0.02, which corresponds roughly to a carbon content of 0.02 pct by weight. The tempering curves did not show any observable sign of a double stage character at any temperature. The half time value for well annealed material was about 2-3 hr at 100°C , about 2 min. at 200°C , and about 10 sec at 300°C . For higher temperatures precipitation was so rapid that we were able to observe only the final equilibrium values.

FIG 7—Aging history of specimens whose micrographs are given in Fig 8.

Table 1 . . . Solubility of Carbon in Alpha Iron in Equilibrium with Fe_3C .

| t ($^\circ\text{C}$) | 250° | 400° | 450° | 500° | 550° | 600° | 650° | 700° | 710° |
|--|-------|-------|-------|-------|-------|------|-------|-------|-------|
| $Q_{\text{max}}^{-1} \simeq [\text{c}]_{\text{sat}}$ | 0.001 | 0.002 | 0.003 | 0.004 | 0.007 | 0.01 | 0.012 | 0.016 | 0.020 |

These data are plotted in Fig 9 and from the slope of Curve 3 we calculate for the heat of solution of Fe_3C in α -iron about 10,000 cal per mol.

The above determined values of the solubility of C in α -iron with respect to Fe_3C are only about one-half the values reported by Köster.⁷ The extrapolated value at the eutectoid temperature of 723°C obtained from the above data is, however, in excellent agreement with the value of 0.025 wt pct given by Smith⁹ from an extrapolation of his higher temperature data on the equilibrium of C in α -iron with C in γ -iron.

Results of Microscopic Investigation

A specimen purified of C by wet H_2 treatment was loaded with N. The initial value of Q_{max}^{-1} was 0.049. The tempering curve for 250°C is shown in Fig 7. After a re-solution heat treatment the tempering treatment at 250°C was repeated. Micrographs of the various stages during tempering were made on small samples cut from the quenched specimen after increasing tempering periods. Some of them with tempering times indicated by arrows in Fig 7, and which were most characteristic, have been reproduced in Fig 8 (a-d). No micrographs were taken for other tempering temperatures. The magnification was $500\times$; the etchant was

pical. The big dark spots are oxide impurities. After some seconds the micrographs reveal the very early stages of some visible precipitation process. After 1 min., when the first equilibrium state in Fig 7 is reached, these early stages have developed into a highly dispersed but well-defined structure shown in Fig 8a. The measured distance between the dark etched N-rich regions is about 10^{-4} cm. This value is consistent with the calculated diffusion distance X according to $X = \sqrt{Dt}$, in which t is tempering time in seconds and the atomic diffusion coefficient² D is $5.2 \times 10^{-4} e^{-20,000/RT}$ $\text{cm}^2\text{sec}^{-1}$. From the initial concentration of about 0.05 pct N we now calculate easily that the thickness of the platelets precipitated must be of the order of 10\AA , assuming that each observed platelet is not a series of smaller parallel platelets. That they nevertheless show up so markedly in the micrograph must be an etching effect which is probably due to the fact that a large region around the precipitate is in a state of high internal strain caused by the precipitate itself.

Though Fig 7 shows that no further precipitation from the α -Fe phase takes place for tempering times between 1 and 30 min., successive micrographs during this period demonstrate that the structure has not reached a steady state. The distance between the platelets gradually increases, presumably due to a coagulation process. After 30 min. the regular geometrical pattern

FIG 8—Illustration of two types of precipitates: *a* and *b*, intermediate phase; *c*, intermediate and Fe_4N phase; *d*, Fe_4N phase. Aging history given in Fig 7. $\times 500$. Reduced approximately one third in reproduction.

of Fig 8*b* is obtained. Similar platelike structures arranged along definite crystal planes (the so-called Widmanstätten structures) are quite common in precipitation phenomena¹⁰ though their explanation is still unsatisfactory. Very often the dark etched regions consist of a series of mostly parallel, close, rather short plates, which cause the wavering character of the etching marks.

The pattern in Fig 8*b* generally shows no more than 3 different orientations of the plates, and from simple geometrical considerations it is clear that these plates of a precipitated Fe-N phase must be arranged parallel to the (100) planes of the bcc iron matrix. Very often the polishing plane itself is parallel to a (100) plane and then the Widmanstätten pattern shows only 2 orientations at right angles, as in some of the crystal grains in Fig 8*b*. Moreover, in this case the polishing plane sometimes cuts just across a plate in its own plane and we see round etched areas which are vaguely visible in the rectangular spaces between the dark

lines; they do not show up well in the micrographs. They prove that the precipitate is indeed plate-shaped and not needlelike. The thickness of these plates must be of the order of 50 Å. Micrographs made of these tempered specimens after a second anneal at 600°C followed by quenching (re-solution heat treatment) did not show any trace of precipitate in accordance with the internal friction measurements.

At this time and even earlier a new precipitate (indicated by II to distinguish it from the former precipitate I) suddenly develops here and there. It is easily observed because it etches much darker with picral than I. Precipitate II almost directly shows the well known plate structure of the iron nitride Fe_4N . Fig 8*c* corresponds to a tempering time of 40 min. During the second drop of the curve in Fig 7 the micrographs show that the number and size of the Fe_4N plates increase, while phase I is fading away, especially in the vicinity of the Fe_4N plates.

After 1 hr phase I is still visible, al-

though only faintly; after 3 hr of tempering we distinguish only the Fe_4N plates (Fig 8*d*). The Widmanstätten patterns of phase I and Fe_4N are quite different. The large number of different orientations of the "nitride needles" in Fig 8*d* indicates that the lattice planes of the matrix along which the plates of the phase Fe_4N are arranged must be of a higher order. According to the literature¹¹ Fe_4N precipitates in plates along the (210) plane of the bcc matrix lattice, which generally causes 12 different orientations of the needles in the micrograph.

We were not able to detect any clearly pronounced relationship between the two precipitates. The Fe_4N plates seem to originate from nuclei inside or very close to the plates of phase I as well as somewhere else. The fact that the phases I and II precipitate on quite different lattice planes of the matrix is reason to suppose that there exists no definite relationship and that phase I is not an intermediate transition state of phase II, as for in-

stance is observed in the precipitation of Cu and Ag in Al.¹² We thus see that this microscopic work confirms the conclusions in section 3 regarding the independence of the nucleation of phase II from the presence of phase I.

As mentioned in the preceding section, the curves of internal friction vs. time of tempering did not suggest the presence of an intermediate precipitate in the Fe-C system. Micrographs showing successive stages during tempering at 250°C revealed only small round dots of precipitate which coagulated somewhat during extended tempering times.

Kinetics of Precipitation

Certain observations reported above which, at least on the surface, appear anomalous may be readily understood when cognizance is taken of the standard nucleation theory. This theory has been discussed in great detail by Volmer,¹³ so only the results of the theory need be herein reproduced.

According to the standard nucleation theory the rate of formation of new nuclei, N , is given by the product of two factors each of which depends upon temperature in a characteristic manner. Thus

$$N = DS. \quad [1]$$

The first factor D , known as the diffusion factor, decreases rapidly with a decrease in temperature according to the well known equation

$$D \sim e^{-H/RT}, \quad [2]$$

where H is the heat of activation for the diffusion of the solute atoms. The second factor, S , known as the statistical factor, varies with temperature in a quite different manner, namely as

$$S \sim e^{-T_0^3/T(T_0-T)^2}, \quad [3]$$

where T_0 is the equilibrium temperature corresponding to the concentration of the atoms in solid solution. The temperature T_0 is a function of the geometry of the nucleus, its interface surface tension with respect to the surrounding matrix, and its heat of solution. The precise manner in which T_0 depends upon these parameters need not concern us here. The characteristic manner in which S varies with temperature is determined by the factor $(T_0 - T)^2$ in the denominator of the exponent. This exponent insures that the nucleation factor rapidly approaches zero as the temperature T increases towards the equilibrium temperature.

Reference to Fig 4a, 4b and 6 shows that as the temperature of tempering is gradually increased above room temperature, the time required for precipi-

FIG 9—Concentration of N in equilibrium with intermediate phase (Curve I), with Fe_4N (Curve II), and concentration of carbon in equilibrium with Fe_3C (Curve III).

tation to be half complete, $t_{1/2}$, at first decreases and then finally rapidly increases at the highest temperatures. According to the above discussion, we are to interpret the lower temperature range, in which $t_{1/2}$ decreases with a rise in temperature, as that range in which the temperature dependence of D dominates. Thus in this temperature range precipitation is limited primarily by the rate of diffusion. On the other hand, the upper temperature range, in which $t_{1/2}$ increases with a rise in temperature, is that range in which the temperature dependence of S dominates. Thus in this temperature range precipitation is limited primarily by the statistical probability of the presence of nuclei of a critical size for spontaneous growth.

Reference to Fig 3 shows that the time for precipitation to be half complete, $t_{1/2}$, is a marked function of the concentration of the solute atoms, rapidly increasing as the concentration is lowered. The same conclusion is reached upon comparing Fig 6 with Fig 4a. This marked dependence of $t_{1/2}$ upon initial concentration may be

interpreted simply as an increase in T_0 with an increase in concentration at a fixed temperature of tempering. Such an increase in T_0 may be seen, from Eq 3, to result in an increase in the statistical factor S . Thus an increase in initial concentration is seen to affect S in precisely the same manner as a decrease in temperature, namely through an increase in the temperature of undercooling, $(T_0 - T)$.

Specimens in which the N precipitates at 23°C in some hours can be stabilized by a preceding tempering treatment at, for example, 250°C. By this we mean that the rate of precipitation at 23°C, after a preceding tempering treatment at 250°C which took out let us say 60 pct of N from solid solution, is much smaller than if the same amount had been rejected from solid solution during preceding aging at 23°C. The explanation must be the different degree of dispersion of the nuclei. It is to be noted that the rate of nucleation is very slow at 23°C after 60 pct of N has been rejected from α -iron.

FIG 10—Equilibrium diagram of Fe-N system including metastable intermediate phase.

We have yet to interpret the formation of the intermediate phase in the Fe-N system. A tentative interpretation may be arrived at as follows. From our observations it appears that the Fe_4N phase is very difficult to nucleate. The origin of this difficulty is at present unknown. It may possibly reside in an unusually large interface energy between Fe_4N and the surrounding α -iron matrix. Reference to Fig 1 shows that if the solid solution of N in α -iron is sufficiently undercooled the solution will become supersaturated with respect to the ϵ -phase. This possibility is clarified by the tentative equilibrium diagram of Fig 10. According to this diagram the dashed boundaries of the α and ϵ phases represent the actual boundaries in the absence of the Fe_4N phase. The dashed boundary of the α phase has been drawn from the data in Fig 9. The dashed boundary of the ϵ phase has been drawn merely schematically.

The above interpretation of the intermediate phase in the Fe-N system automatically interprets likewise the nonoccurrence of an intermediate phase in the Fe-C system. In the latter system the only stable phase lying to the right of Fe_3C is graphite. This phase actually has a lower solution pressure than does Fe_3C . It could not, therefore, form an intermediate phase.

Effect of Cold Work

It is a well known experimental fact that distorted regions are favorable places for precipitation. The reason was pointed out above. An amount of cold work of 1 to 5 pct reduction in area did not have very much effect on the rate of precipitation of N from supersaturated α -iron. Certainly the

distances between the distorted regions for this small amount of cold work are too large to affect the precipitation in the specimen as a whole. The effect of 46 pct reduction in area was previously shown in Fig 3. Micrographs of these cold worked specimens being tempered in the region 250–300°C did not show any trace of precipitate. This means that it must be and stay submicroscopically dispersed even at 300°C and that this precipitate modification must be more stable than the usual microscopic Fe_4N plates. A determination of the solubility of N for this precipitate, by the internal friction measurements, indeed proved this to be the case. The solubility at 300°C was about 0.0025 pct, at 400°C about 0.006 pct, while the corresponding values for the Fe_4N plates were respectively 0.012 and 0.025 pct. At higher temperatures the solubility very rapidly increased, partly in an irreversible way due to the fact that the state of cold work is gradually annealed out.

The observed lowering of the solubility of N by plastic deformation is in agreement with the idea advanced by Cottrell that carbon and nitrogen are trapped by dislocations.¹⁴

Summary

Precipitation of carbon and of nitrogen from solid solution in alpha-iron has been studied at different tempering temperatures by internal friction measurements.

In the case of nitrogen these measurements suggested the presence of two successive stages in precipitation. This suggestion was then verified by metallographic examinations. In the first stage plates of an unknown precipitate are formed on the (100) planes of the

matrix. During the second stage the well known Fe_4N plates are formed. The former unknown phase appears to be less stable than Fe_4N , but cannot be considered as a transition state of Fe_4N .

The observed rate of precipitation follows the general behavior to be anticipated from the standard theory of diffusion and nucleation, namely low rates at low temperatures (diffusion limitation), low rates at high temperatures near the critical temperature (nucleation limitation) and a maximum rate in an optimum temperature range. The half time for precipitation is found to increase rapidly with a decrease in the initial concentration, again in accord with nucleation theory.

Plastic deformation (studied only in the case of N) was found not only to increase the rate of precipitation, but also to lower the final solution concentration presumably in equilibrium with the precipitate. It appeared, therefore, as if the precipitate induced by plastic deformation was not identical to that which forms in annealed material. This viewpoint was confirmed by metallographic examination which failed to reveal visible precipitates even after the final equilibrium solute concentration had been attained.

Concentration of the SO₂ Content of Dwight-Lloyd Sintering Machine Gas by Recirculation

W. S. REID,* Member AIME

IN March, 1938, E. P. Fleming, metallurgist for the American Smelting and Refining Co. inaugurated an investigation into the possibilities of recirculating the gases from Dwight-Lloyd sintering machines operating on lead charge, with the twofold object of concentration of the SO₂ content and reduction in volume of total gas produced.

The possibility of recovering a commercial grade of SO₂ gas from D & L machines operating on lead charge had previously been considered by several investigators.

Early History of Recirculation

The Selby Smelter Commission Report, published by the Bureau of Mines in 1914, contains a chapter by A. E. Wells regarding results obtained at Selby, wherein some of the richer gas was recirculated through a hood over the pallets.

Oldright and Miller of the U. S. Bureau of Mines had also made tests at Trail, B.C., and at Kellogg, Idaho.

R. C. Rutherford, while at the Chihuahua, Mexico, Smelter of the American Smelting and Refining Co., in May, 1937, proposed recirculation of D & L gases to decrease the volume of gas handled by the baghouse.

At none of these plants, however, was the operation commercialized.

In July, 1938, Mr. Fleming, in correspondence with the Selby Plant, inquired regarding the possibility of obtaining 6 pct SO₂ gas from the Selby D & L machines.

At that time, the writer advised that there was slight possibility of obtaining 6 pct SO₂ gas without re-

circulation, but believed that it was possible with recirculation, and that experimental work toward that end should be tried at some plant where spare D & L machines were available.

The foregoing statement was based on the following information then available—

1. Tests on Selby first-over machines showed 2.28 pct SO₂ from first windbox and 1.03 pct SO₂ from second windbox, and corresponding figures for second-over charge of 0.81 pct SO₂ for first windbox and 0.08 pct SO₂ for second windbox.

2. Oldright and Miller (U.S. Bureau of Mines) in 1932 at Bunker Hill, on 42 in. × 22 ft machines found:

a. First-over charge—Maximum SO₂ concentration (leaving cake) of 9.5 pct.

b. First-over charge—SO₂ concentration of over 8 pct from the 4 ft to the 12 ft points beyond the front deadplate and that the concentration then dropped rapidly.

c. That approximately 80 pct of the total sulphur eliminated on the second-over machines occurred during the travel of the pallets from the 1 ft to the 6 ft distances from the deadplate.

d. That approximately 94 pct of the total sulphur eliminated on the second-over machines occurred over the first windbox.

3. Oldright and Miller (U.S. Bureau of Mines) in 1932, at Trail, on 42 in. × 50 ft machines found:

a. First-over charge—SO₂ varied

FIG 1—Sulphur elimination curve.

from 2.0 pct to 5.5 pct (leaving cake) from the 12 ft to 28 ft points from the deadplate.

b. That the average SO₂ increased from 1.0 pct at 7 ft from deadplate to maximum of 3.3 pct at 20 ft, then dropped to 1.5 pct at 40 ft.

c. That on a 22 ft, second-over machine with an 11 in. bed the SO₂ varied from 4.5 pct to 6.5 pct from the 2 ft to the 8 ft points from the deadplate.

d. That on the final roast, the SO₂ concentration also varied across the pallets; that is, 2½ pct at the side, increasing to 6.0 pct, 5 in. in, and to 7.0 pct at 10 in. to 20 in. in, then decreased vice versa at the opposite side.

e. Concluded that most of the sulphur on a 22 ft machine was removed over the first 7 ft of the first windbox; therefore, they partitioned the first windbox so that the exit gas from the second 4 ft section was returned to the surface of the pallets over the first 7 ft section, and during a seven-day trial the gas from the 4 ft section averaged 2.4 pct SO₂, while the recirculated gas from the first 7 ft section only increased to 3.8 pct SO₂. (Excess suction over the 7 ft section to prevent escape of SO₂ laden gas from the 4 ft section caused dilution by air.)

San Francisco Meeting, February 1949.

TP 2554 D. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before July 15, 1949. Manuscript received Nov. 14, 1948; revision received January 11, 1949.

* Selby Smelting Works, American Smelting and Refining Co., Selby, California.

f. That recirculation had the advantage of filtering out the dust contained in the recirculated gas.

g. That second-over charge on a 50 ft machine gave SO₂ concentrations ranging from 2.4 pct at 6 ft to 4.0 pct at 8 ft; to 5.0 pct at 10 ft, to 4.6 pct at 12 ft; to 4.3 pct at 22 ft; to 2.0 pct at 26 ft; to 1.0 pct at 30 ft; to trace at 34 ft from deadplate.

If the figures under g are plotted, we have what is now known as a sulphur elimination curve, which is shown in Fig 1.

Preliminary Work at Selby

At the Selby, Calif., Plant of the American Smelting and Refining Co., the company, since 1937, had been operating a 40-ton per day Contact Acid Plant on gases from the roasting of pyritic gold concentrates on a seven hearth Wedge Roaster. This conversion of SO₂ to H₂SO₄ was beneficial in reducing the output of SO₂ from the smoke stack.

At that time (1938) some consideration was also being given to the construction of a liquid sulphur dioxide plant to utilize still more of the SO₂, normally exhausted through the stack.

During Sept., 1938, the first investigation was made at Selby in connection with the feasibility of obtaining a good grade of SO₂ gas from the D & L machines.

Holes were drilled in the sides of various pallets in such a manner that a sample pipe could be inserted to the center of the bed, just under the grate bars. Gas samples taken through the pipe, as the pallets passed over the windboxes, were then analyzed for SO₂.

These first tests on a 42 in. x 22 ft D & L machine, operating with a 4-in. bed at a pallet speed of about 29 ipm, 25 to 30 pct return sinter on a very fine charge, with windbox suction at 12 in. to 12½ in. H₂O, fan volume at 17,500 cfm, and sulphur in charge reduced from 13.0 pct to 5.3 pct, showed as follows for the first windbox: Pct SO₂ under grates—4.6 pct to 9.2 pct—Average—7.4 pct Pct SO₂ leaving windbox—1.1 pct to 1.35 pct—Average—1.25 pct

It was obvious that the principal source of air leakage was between the pallets and the windbox and over the deadplates, with smaller amounts through the shrinkage fissures at the junction of the sinter cake with the side of the pallet, between the pallet

FIG 2—First-over charge—12 pct sulphur.

FIG 3—Second-over charge—4.5 pct sulphur.

ends, and around windbox cleanout doors, and the like.

The second windbox on the same charge showed SO₂ concentrations under the grates varying from 6.5 pct to 10.0 pct, and averaging 7.8 pct.

These tests indicated that on this very tight charge, the sulphur elimination continued high throughout the length of machine.

Tests were then made on a second-over machine, operating with a 5¼ in. bed at 19 ipm speed, with windbox suction at 6½ in. H₂O, and fan at 15,000 cfm. These tests showed peak sulphur elimination about midway of the first windbox, after which it dropped rapidly as the pallets passed to and across the second windbox.

A typical set of SO₂ readings showed 2.3 pct SO₂ at the 2 ft mark, a peak of 5.5 pct midway of the first windbox, then decreasing amounts to the second

windbox, which averaged only 0.15 pct for its entire length. It was evident that the first windbox was doing about 90 pct of the work as far as actual sulphur elimination was concerned. The second windbox was serving, principally, as a cooler for the hot sinter cake.

These preliminary tests clearly indicated that, in order to secure a good grade of SO₂ gas, it would be necessary to recirculate the intermediate grade gas through hoods covering the entire pallet including ends and the sealing strip, and collect the concentrated gas from a relative short section of the machine where the SO₂ concentration was highest.

Preliminary Work at Murray

Further experimental work along the lines of Mr. Fleming's suggestion was performed under the supervision of Mr. A. L. Labbe at the Murray, Utah, Plant of the American Smelting and Refining Co. This work was started in Nov., 1938, on standard 42 in. x 22 ft D & L machines on both first-over and second-over charge. By taking gas samples from 2 in. below the grate bars as the pallets passed over the windboxes, the SO₂ concentrations at various points along the machine were determined.

Fig 2 shows, in graphic form, the resultant data for a "first-over" charge and Fig 3, the same for a "second-over" charge.

These graphs illustrate how the SO₂ concentration increases to a peak about midway of the first windbox and then rapidly decreases as the pallets proceed to and over the second windbox.

The comparison of strength of gas under the pallets vs. strength of gas in the outlet from the windbox brings out the often overlooked fact that an unbelievably high leakage of air occurs under and around the pallet ends and over the deadplates. The following tabulation, based on the foregoing data, might demonstrate more clearly this high leakage factor of the ordinary D & L machine:

| | First Windbox | | | Second Windbox | | |
|-------------------------|----------------------------------|-------------------------------------|-----------------|----------------------------------|-------------------------------------|-----------------|
| | Pct SO ₂ Under Grates | Pct SO ₂ Leaving Windbox | Pct Air Leakage | Pct SO ₂ Under Grates | Pct SO ₂ Leaving Windbox | Pct Air Leakage |
| First-over Charge..... | 8.6 | 3.1 | 277 | 2.5 | 1.7 | 147 |
| Second-over Charge..... | 5.4 | 2.0 | 270 | 0.52 | 0.25 | 208 |

Or, for the machines as a whole:

First-over Charge—231 pct air leakage

Second-over Charge—263 pct air leakage.

Later tests on varying charges, depths of bed, and others, indicated air leakages varying up to 400 pct.

Recirculation at Murray

In March, 1939, the first actual recirculation of gases at Murray, Utah, was tried out on a standard 42 in. \times 22 ft D & L machine. This initial installation consisted of a recirculation fan, which delivered the gases from the second windbox through a duct to a hood over the pallets on the first windbox. On a firstover charge, carrying 11.0 pct S, it effected an SO_2 concentration averaging 5.1 pct SO_2 in the reduced volume of gas delivered to the Cottrell flue. However, this final gas varied from 4.0 pct SO_2 to 6.5 pct SO_2 , depending on variations in the moisture content and uneven porosity of the bed. The uneven porosity was due principally to segregation of coarse and fines in the charge hopper above the machine.

This first trial installation also demonstrated the importance of a baffle plate over the windbox partition to minimize the interchange of the weak and strong gases, and, likewise, the partitioning of the conventional windboxes, or construction of different sized windboxes to obtain the maximum concentration of the SO_2 .

To summarize, this first trial installation effected the following on first-over charge:

Gas volume reduced from 19,000 cfm to 6,850 cfm.

SO_2 concentration in final gas increased from 1.7 pct to 5.1 pct.

At this time, it was realized that the same proportional decrease in volume would not be possible from a wider machine because the volume resulting from side leakage is approximately the same regardless of the width of the machine.

This initial installation at Murray is still in service, but utilized solely to decrease the volume of gas going to the Cottrell treaters.

Patent

Based upon data obtained on this preliminary work, Mr. Labbe applied

for, and was subsequently granted, U. S. Patent No. 2,235,261, entitled, "Method and Apparatus for Sintering."

Prior commercial applications of utilizing the oxygen content of weak gas for additional roasting, or in effect further concentration of the SO_2 content of these gases, had accomplished their purpose by returning the weak gases from the last windbox to a closed hood over a limited central section. Attempts on a two-windbox machine to return the gases to a hood confined over the sinter bed of the first windbox had failed, due to the SO_2 in the circulated gases smothering the combustion in the sinter bed proper.

The main features of the sintering machine of Mr. Labbe's patent may be summarized as follows:

Although it is applicable to multiple windbox machines, its application to a two-windbox machine is described merely for simplification.

A hood is provided over most or all of the bed, including pallet ends and wheels, over the second windbox and a large proportion of the first windbox. It cannot be extended any farther over the first box on account of the ignition muffle. The hood also extends over the discharge end of the machine.

There are no cross-sectional baffles in the hood to confine the direction of the smoke to any one portion of the sinter bed. The smoke is free to establish its own course or equilibrium over the entire surface of the sinter bed. Part of the circulated smoke may be drawn back through the same bed of the second windbox.

An inner hood with an opening adjacent to the ignition muffle extends back under the recirculation hood proper, for a distance, over the sinter bed of the first windbox. This allows some outside air to enter and freely support combustion, yet diverts the

FIG 4—Data obtained over 5-day period on a first-over charge averaging 10.5 pct S.

recirculated gas around the ends of the pallets and thus substitutes this SO_2 laden gas for the air that is ordinarily drawn in as leakage on an unhooded machine.

Trial Recirculation at Selby

By Sept. 1939, the D & L machines at Selby had been enlarged, the sintering practice improved and serious consideration was being given to the utilization of D & L gases for the production of liquid SO_2 .

As a result, a new series of tests were made on the gases by taking samples from under the grate bars by inserting a sample pipe through holes near the top of the various windboxes. A sulphur elimination curve depicting the average data obtained over a 5-day period on a first-over charge averaging 10.5 pct is shown in Fig 4.

While this sulphur elimination curve showed a 15-ft section of the machine producing better than a 5 pct concentration of SO_2 , the actual SO_2 concentration leaving the windboxes averaged only 2.1 pct. This indicated a high infiltration of air around windbox seals, between the pallets at the side of the machine, over the deadplates, and through the shrinkage space between the bed and sides of the pallets.

This machine was reducing 200 tons of charge from 10.5 pct S to 4.5 pct S per day with the fan handling a volume of 25,000 cfm at 440°F.

Gas concentration from the windboxes varied widely, depending on the nature of the charge. A tight charge increased the air leakage, thereby decreasing the SO_2 content of the gases leaving the windboxes. Variations in the depth of the bed on various machines resulted in SO_2 concentrations varying from 0.6 pct to 2.32 pct.

The first trial recirculation unit at

FIG 5—Recirculated gas.

Selby was completed and put into service on May 10, 1940, and consisted of a No. 9 Type P. B. American Blower Co. Exhauster Fan for concentration of the SO_2 content of the gas from a three-windbox D & L machine, 42 in. wide \times 30 ft long, operating on "first-over" charge.

The design for this recirculation unit, including the location of the hoods, was based upon the sulphur elimination curve for the average charge handled by the machine. The so-called sulphur elimination curve, or a knowledge of the data from which it might be drawn, is fundamental in designing a recirculation unit. The pattern varies with different sized machines and with variations in the charge on the same sized machines.

The sulphur elimination curve of a machine on "first-over" charge is quite different from the same sized machine or "second-over" or final charge.

The procedure which has been developed for making a sulphur elimination curve is as follows: 1. Have D & L machine operating normally, with uniform feed.

2. Determine SO_2 content of gases directly under the grate bars at intervals throughout the passage over the windboxes.

Under (1) it is important that the charge be uniform as to analyses, size and moisture content, as well as being uniformly laid down on the pallets. Uniformity of material on the pallets is of major importance because it is impracticable to take and determine gas samples from numerous points throughout the length of the machine simultaneously. As the gas samples must be taken progressively, it is obvious that conditions must be comparable during the entire sampling period. Particular care should be exercised to prevent major segregation of coarse and fines in the feed hoppers

over the machine, yet at the same time obtain a uniform segregation of coarse and fines as the charge is laid down on the pallets. This last mentioned condition is secured by proper design of the feeding mechanism and close control of the talus pile. A high talus pile usually causes "sloughing" which results in a spotty bed, while a "low" talus pile tends to "break" the segregation, which is so desirable at this point.

Under (2) the actual data for plotting the sulphur elimination curve is obtained by sampling the gas directly under the grate bars. In actual practice, these samples are now taken by inserting a curved pipe through openings near the top of the windboxes, allowing same to follow the travel of the pallet a sufficient length of time to draw a measured volume of gas sample through an iodine solution for analysis. In this manner, a sample is obtained which is undiluted by the enormous air leakage normally occurring under and around the ends of the pallets. By taking several of the samples at each location, the average SO_2 concentration at this particular point may be determined and from this a sulphur elimination curve may be plotted.

This first recirculation unit at Selby was entirely for experimental purposes as no utilization of the concentrated gas was made.

The first-over machines at that time were delivering up to 28,000 cfm of approximately 1.5 pct SO_2 gas to the baghouse. This grade of gas was entirely too low in sulphur dioxide to maintain the conversion temperatures at the Contact Acid Plant.

The 42 in. machine equipped for this experimental work had three windboxes, the first box being 8 ft long and the second and third boxes, 11 ft each. The gas from the No. 3 box was returned by the recirculation

fan to a hood over part of No. 1 box and all of No. 2 box, as indicated in Fig 5.

It was soon learned that maintaining proper balance of draft in the recirculation hood was essential. Actual pressure in the recirculation hood caused a smoke nuisance in the building. Excess draft permitted infiltration of air and resultant dilution of the concentrated gas. A definite drop in the concentration was noted whenever the draft in the recirculation hood exceeded 0.02 to 0.03 in. water. This precise regulation was later accomplished by the installation of a damper controlled by a Bristol free-vane controller. Recording draft gauges were also installed in the various windboxes and an SO_2 recorder installed to indicate and continuously record the SO_2 concentration in the concentrated gas.

On the first-over charge, averaging about 13.0 pct S, the recirculation fan handled a volume of 5,000 to 9,000 cfm at temperatures ranging from 700 to 800°F.

By close attention to all operating details, it was demonstrated that with the high sulphur charge being handled at that time gas concentrations of 6 to 8 pct SO_2 could be obtained, but that with this degree of concentration the speed of the machine was reduced about 10 pct in order to effect the same overall sulphur elimination. Overall gas volume to the baghouse with recirculation was approximately 11,800 cfm at 385°F, as compared to approximately 23,100 cfm at 330°F without recirculation. Subsequent improvements in the windbox, duct, and hoop designs corrected this loss in tonnage feature. The first step was to by-pass part of the gas from Windbox No. 3 to the main fan, as indicated by the dotted lines in Fig 5. This practically doubled the suction in Windbox No. 3 and equalized it with No. 1 and No. 2 Windboxes.

FIG 6—Schematic diagram of first-over recirculation.

These preliminary tests, along with the sulphur elimination curve of the machine indicated that the installation of partitions in the first and third windboxes, whereby the weak gas from the end sections could be segregated and by-passed direct to the baghouse, would be advisable. These tests also showed that when recirculating approximately 3,000 cfm the total fan power consumed was about 69 hp, as compared to 60 hp with the machine operating normally, that is, without recirculation.

During April, 1942, an improved recirculation system for the first-over machine at Selby was completed and further tests proceeded. This new installation consisted of a recirculation fan which drew the recirculated gases through a series of vertical pipe coolers before returning them to the hoods over the pallets. This cooler was later abandoned. The windboxes were also subdivided.

Fig 6 shows a diagrammatic flow sheet of the gases and sizes of various windboxes.

This layout demonstrated that when handling a raw feed mix, averaging 12 pct S, the machine would produce an average of 5,900 cfm at 310°F, of 7.0 pct SO₂ gas for possible utilization at an acid or SO₂ plant.

The concentration of SO₂ varied with the charge, depending largely on the physical characteristics and also on the proportion of sulphide sulphur in the raw feed. Sulphur present as pyrite, for example, was much more desirable than a charge in which part of the sulphur was present as sulphate. Low SO₂ in the concentrated gas invariably accompanied high volume and vice versa. For example:

7.0 pct SO₂ (20 tons S per day)—

Volume, 6,400 cfm at 250°F

8.75 pct SO₂ (16 tons S per day)—

Volume, 5,200 cfm at 330°F

Volume of the recirculated gas varied with the charge between limits as follows:

4.0 pct SO₂—3,500 cfm at 400°F

7.0 pct SO₂—1,500 cfm at 300°F

The distribution of volumes was roughly as follows:

| | |
|--|---|
| First Windbox (4 ft long)..... | Cfm |
| Middle Windbox (concentrated gas)..... | 3,000 |
| Recirculation Windbox (net)... | 5,900 |
| Last Windbox..... | 1,500 |
| Main Bistle Pipe and Fan Leakage..... | 3,500 |
| | 1,100 |
| Total Volume at Main Fan.... | 15,000 at 375°F and 4.5 pct SO ₂ |

Leakage between the deadplate and the pallets was largely accountable for

the high volumes from the end windboxes.

Test runs over a period of months on this machine indicated that, with a charge averaging about 11.0 pct S, it was possible to produce approximately 6,300 cfm of 7.0 pct SO₂ gas, leaving the middle windbox. This amounted to about 18.8 tons of S per day, or sufficient to produce around 50 tons of H₂SO₄ per day.

Commercial Recirculation at Selby

By the middle of 1942, the War Production Board's famed Order L-208 had seriously curtailed the production of pyritic gold concentrates from the California gold mines. High sulphur concentrates, formerly received in excess of the capacity of the one Wedge roaster at Selby dwindled to the point where lower sulphur concentrates containing lead and zinc had to be substituted in order to keep the 40-ton per day Contact Sulphuric Acid Plant supplied with SO₂ gas. However, the gradually decreasing receipt of pyritic concentrates was acutely curtailing the production of sulphuric acid, which was a critically needed war supply. Barren pyrite was even being used at a loss to enrich the Wedge charge.

As a result of the urgent need for sulphuric acid and based upon the favorable results obtained on the experimental recirculation unit on the D & L machine, an appropriation request was filed in Aug. 1942, to equip a second machine with a recirculation unit and to collect and convey the concentrated gases from both machines to the sulphuric acid plant.

This application was made during the height of difficulties in obtaining priority ratings from the War Production Board. However, after much red tape, preparation of minutely detailed lists of materials, substitutions of used motors, and other procedures, an A-1-A Rating was finally obtained and the work got under way, late in 1942.

Wartime delays in delivery of materials and equipment postponed completion of this unit until March 8, 1943.

The D & L gas was at first mixed with the Wedge gases, but after 26 hr operation it was apparent that special conditioning of the D & L gases would be required in order to recover any

appreciable amount of the solids in the Cottrell treater through which the Wedge gases had previously been treated.

Conditioning equipment, consisting of water sprays, and SO₃ gas, direct from the Acid Plant, was installed in the distribution chamber ahead of the Cottrell (Plate) Treater and considerable work done in closing up leaks in the Cottrell unit and the flue system.

For the next three months, the Acid Plant alternated periodically from D & L to Wedge gases as various operating "bugs" were discovered and corrected.

Starting on July 26, 1943, the Acid Plant operated regularly on D & L gas from first-over machines with the Wedge utilized merely as a standby unit to keep the Acid Plant going during occasional periods when the Sinter Plant was shut down.

Since that time, the 40-ton per day Contact Acid Plant has continued to operate on D & L gases concentrated by recirculation.

Sulphuric acid made from SO₂ gases originating from a straight pyritic concentrate roasted in a multiple hearth roaster is normally water-white in color. However, when the supply of pyritic gold concentrates began to dry up and complex flotation concentrates were substituted, it was noted that the resultant sulphuric acid was, at times, discolored, and with greater percentages of the complex concentrates on the charge the acid was close to a coffee-brown in color.

It is believed that this color imparted to the sulphuric acid is caused by hydrocarbons originating from flotation reagents which carry through the scrubbing towers, mist precipitators and coke filters to the drying tower, where they are picked up by the drying acid and act as a dye to all acid produced.

The colloidal carbon imparting the color is so finely divided that no settling as a sediment ever takes place. It is more in the nature of a dye, and in no way lowers the purity of the acid or decreases its usefulness in the normal commercial uses to which it is put. However, as this discoloration is objectionable to certain customers, particularly the food processing plants, it was deemed desirable to clarify the product and a method for so doing has been devised by Mr. Walter F. Johnson, Research Dept. metallurgist.

FIG 7—Sulphur elimination curve showing typical graph of data obtained.

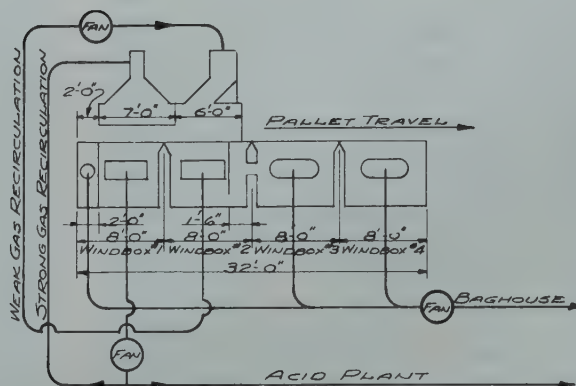

FIG 8—Schematic diagram of second-over recirculation.

In May, 1945, a new recirculation system on a 63 in. \times 32 ft, "second-over" D & L machine was completed. This unit consists of two 10,000 cfm fans, hoods, ducts, control instruments, and other items.

This installation was made for the threefold purpose of (1) obtaining practical operating data on second-over charge; (2) supplemental SO_2 supply for the acid plant; and (3) SO_2 supply for a liquid sulphur dioxide plant to be constructed at some future date.

Prior to designing the recirculation unit for this 63 in. second-over or Final Product Machine, numerous tests were made to determine the sulphur elimination characteristics.

The sulphur elimination curve in Fig 7 shows a typical graph of the data obtained.

It will be noted that this sulphur elimination curve is quite different from the curve for a machine handling first-over charge.

Here, after the charge is ignited, the bed roasts rapidly, coming to a peak about midway of the first windbox

and then tapering off rapidly over the second windbox. Very little sulphur is eliminated over the third windbox and practically none over the fourth or last windbox.

Fig 8 shows the windbox and hood design for this machine and a diagrammatic outline of the flow of gases.

Following a preliminary test period, the concentrated gases from this machine were diverted to the Acid Plant on June 18, 1945, and have been utilized periodically since that time to supplement the concentrated gases from the first-over machines.

At the present time, the concentrated gases from the second-over machine are actually higher in SO_2 content than those from the higher sulphur first-over charge.

In Sept. 1947, a 15-ton per day liquid sulphur dioxide plant was completed at Selby and, since that time, both the sulphur dioxide plant and the sulphuric acid plant have been operated entirely on D & L lead charge gases, concentrated by recirculation.

The sulphur dioxide plant is not dependent on a certain grade gas, as is

the contact acid plant. It will function on any strength gas from the roasters and operates smoothly and efficiently on the 5 to 6 pct SO_2 in the gases normally produced by the recirculation units on the Dwight-Lloyd machines.

The SO_2 plan is a patented process,* developed by the American Smelting and Refining Co. Research Dept., under the able direction of Mr. E. P. Fleming. It functions by the absorption of SO_2 in dimethylaniline flowing counter current to the gas stream in a tower consisting of a series of bubble-cap trays. The pregnant D.M.A. solution then goes to a stripping tower where the SO_2 is expelled by boiling with steam heated calandrias. The wet SO_2 gas is dried by passing through sulphuric acid in a third bubble-cap tower, then compressed to liquid and transferred to storage tanks from which the entire production is shipped in railroad tank cars.

* U.S. Patents Nos. 2,295,587 and 2,399,013.

The Crystal Structure of Ni₄W

E. EPREMIAN* and D. HARKER†

THE constitution of the nickel-tungsten system has been studied by a number of investigators, the most recent of which are Ellinger and Sykes.¹ On the basis of metallography, electrical resistivity and hardness measurements and some X ray diffraction work, they constructed a constitution diagram (Fig 1). Ellinger and Sykes report a_0 for the alpha face-centered cubic phase (nickel saturated with tungsten) as 3.66\AA .[‡] The gamma phase (tungsten saturated with nickel) is given as body-centered cubic, but no value of a_0 is recorded. At 43 pct tungsten by weight (approximately 20 at. pct) a beta phase is reported, but structure and lattice parameter are not known. Primarily on the basis of metallographic evidence, they conclude that beta is a new phase and rule out the possibility of formation of a superlattice since they observe a new phase in the microstructure.

Grube and Schlecht² report an ordering reaction in a system similar to the Ni-W (Ni-Mo) and Harker³ has shown that Ni₄Mo forms a superlattice upon the pre-existing face-centered cubic lattice of the alpha phase. Ellinger and Sykes observed a change in the diffraction pattern of a 43 pct W alloy upon aging and attributed it to the formation of a new phase.

Thus, there appears to be some question as to the character of the beta phase reported by Ellinger and Sykes. The purpose of the present work is to determine precisely the structure and nature of the beta phase in the Ni-W system of X ray diffraction methods.

Experimental Procedure

One inch diameter ingots of 43.66

[‡] Distances are reported in true angstrom units throughout this work. Distances in kX must be multiplied by 1.00202 to give distances in angstroms.

FIG 1—Constitution diagram of the nickel-tungsten system after Ellinger and Sykes.

pct, 40.15 pct and 34.06 pct tungsten by weight (19.8, 17.6 and 14.1 at. pct respectively) were melted and cast under vacuum from electrolytic nickel and pure wire filament grade tungsten. The ingots were soaked for 16 hr at 1300°C in a hydrogen atmosphere furnace, then swaged at this temperature and finally drawn to 0.020 in. diam wire. Some of the bar stock was retained in ½ in. diam rod for hardness and metallographic studies. Wire samples for diffraction work were sealed in evacuated quartz tubes and subjected to the various solution and aging heat treatments in a hydrogen

furnace. X ray photographs were taken in a Debye-Scherrer camera using copper K radiation filtered by nickel foil.

Results

X RAY DIFFRACTION

The lattice parameters of the alpha and gamma phases at saturation were determined by an X ray photograph of the 19.8 at. pct W alloy after solution heat treatment at a temperature well within the alpha-gamma range above the peritectoid temperature (17 hr at 1150°C—oil quenched). The alpha phase was found to be face-centered cubic with a_0 of $3.594 \pm 0.001\text{\AA}$, while the gamma phase was determined as body-centered cubic with a_0 of $3.153 \pm 0.001\text{\AA}$. Exactly the same phases and parameters were obtained with the 17.6 at. pct W alloy for the same solution heat treatment.

Thorough analysis was made of an X ray photograph of a 19.8 at. pct alloy sample in the quenched and aged condition (solution treated 17 hr at

FIG 2—View of the structure of Ni_4W along $[001]$.

1150°C—oil quenched; aged 65 hr at 950°C—oil quenched). An attempt was made to index the lines of the pattern on the basis of a tetragonally distorted face-centered cubic unit cell, but it was found that all of the new lines could not be accounted for. The lattice parameters of the small tetragonal unit cell were determined to be $a_0 = 3.6248 \pm 0.001$ and $c_0 = 3.553 \pm 0.001 \text{ \AA}$ with $c/a = 0.980$.

It was necessary to choose a large tetragonal unit cell in order to assign indices to all of the lines appearing in the pattern. The dimensions of this unit cell are $a'_0 = 5.730 \pm 0.001$ and $c'_0 = 3.553 \pm 0.001 \text{ \AA}$ with $c/a = 0.620$.

The structural relationship between the two cells is shown in Fig 2. The following equations relate the indices of the small cell to those of the true large cell. (Primed indices refer to the new large cell):

$$\begin{aligned} h' &= \frac{3h - k}{2} \\ k' &= \frac{h + 3k}{2} \\ l' &= l' \end{aligned}$$

The volume of the large cell is 2.5 times the volume of the small tetragonal cell, $a'_0 = \left(\frac{5}{2}\right)^{1/2} a_0$ and $c'_0 = c_0$.

Those lines which could be indexed on the basis of the small unit cell have indices for which $2h' + k'$ or $h' + 2k'$ is a multiple of 5. These lines, which are quite sharp and strong, make their appearance by splitting from the lines of the alpha face-centered cubic phase.

The lines were indexed by making use of the relation $\text{Sin}^2 \theta = A(h^2 + k^2) + B(l^2)$ where A and B are constants involving the lattice parameters and

$$\text{wave length (from } \text{Sin}^2 \theta = \frac{\lambda^2}{4} \left[\frac{h^2 + k^2}{a^2} + \frac{l^2}{c^2} \right]).$$

This relation was applied to the $\text{Sin}^2 \theta$ values for several low order planes whose hkl indices were known with certainty to predict the $\text{Sin}^2 \theta$ values for planes with higher indices. The A and B values were fitted with the observed data and the lines indexed. These lines which were newly assigned indices were in turn used to assigned planes of still higher order, the process being repeated until all of the lines were identified. This method gives a self-consistent solution to the data, and automatically provides accurate values of the lattice parameters at values of θ (the Bragg angle) near 90°. It was found that $h + k + l$ for all planes was even, which indicates that the structure is body centered. Table 1 summarizes the results obtained for the ordered structure.

Since the unit cell of Ni_4W is body-centered, and since there are 2 W atoms and 8 Ni atoms in a unit cell, there are three possibilities for the space group of the ordered structure, which are as follows (in the notation of ⁵):

1. $S^2_4 - I\bar{4}$: 2W in 2 (a)
8Ni in 8 (g)
parameters x, y, z
2. $C^5_4 - I\bar{4}$: 2W in 2 (a)
8Ni in 8 (c)
parameters x, y, z

3. $C^5_4h - I\bar{4}/m$: 2W in 2 (a)
8Ni in 8 (h)

parameters x, y

All of these structures have the same projection on the x, y plane, but differ in the projection on the z -axis.

Intensity calculations were made to determine which of the three possible space groups correspond to the structure of Ni_4W . The relative intensities of lines were calculated by means of the following formula:

$$I = \text{Constant } x \frac{1 + \text{Cos}^2 2\theta}{\text{Sin}^2 \theta \text{ Cos } \theta} P_{hkl} F^2_{hkl} A_\theta$$

$\frac{1 + \text{Cos}^2 2\theta}{\text{Sin}^2 \theta \text{ Cos } \theta}$ is the Lorenz and Polarization Factor

P_{hkl} is the multiplicity factor

F^2_{hkl} is the structure factor

A_θ is the absorption factor

θ is the Bragg angle

Since the ordered structure is formed primarily from the alpha face-centered phase, it appeared likely that the atoms would be in an arrangement which is nearly that of cubic close packing. In this case, the approximate positions of the 10 atoms in the unit cell are as follows:

W at $xyz = 000$ and $\frac{1}{2}\frac{1}{2}\frac{1}{2}$
Ni at $xyz = \frac{1}{10} \frac{3}{10} \frac{1}{2}; \frac{3}{10} \frac{1}{10} \frac{1}{2}; \frac{1}{10} \frac{1}{10} 0; \frac{3}{10} \frac{3}{10} 0;$
 $\frac{3}{10} \frac{1}{10} \frac{1}{2}; \frac{1}{10} \frac{3}{10} \frac{1}{2}; \frac{1}{10} \frac{1}{10} 0; \frac{3}{10} \frac{3}{10} \frac{1}{2};$
 $\frac{3}{10} \frac{1}{10} 0; \frac{1}{10} \frac{3}{10} \frac{1}{2}.$

and the space-group is $C^5_4h - I\bar{4}/m$. It is seen that half of these atomic positions are merely lattice translations of the others. Thus, the approximate positions are:

W at 000

Ni at $\frac{2}{5} \frac{1}{5} 0; \frac{1}{5} \frac{2}{5} 0; \frac{3}{5} \frac{1}{5} 0; \frac{1}{5} \frac{3}{5} 0$, that is, at $\frac{2}{5} \frac{1}{5} 0$ and positions derived from this by operation of the four-fold axis.

The structure factor formula for $I\bar{4}/m$ is:

$$F_{hkl} = 2\{f_W + 2f_{Ni}[\text{Cos } 2\pi(hx + ky) + \text{Cos } 2\pi(kx - hy)]\}$$

where f_W is the atomic scattering factor for tungsten

f_{Ni} is the atomic scattering factor for nickel

hkl are the indices of the plane
 xy are the coordinates of one of the Ni atoms.

Using the above structure factor formula in the equation for intensity, and properly taking into account the change in atomic scattering factor, Lorenz factor, and absorption factor with change in the Bragg angle, the intensities of all the lines were calculated. Table 1 includes a comparison between the observed and calculated intensities of the lines for $x = 0.400$,

$y = 0.200$. Complete intensity calculations were made in which x and y were varied in steps of 0.005 between 0.390 – 0.410 and 0.190 – 0.210 respectively. The best agreement was obtained for $x = 0.400$ and $y = 0.200$, which, as is seen, was excellent. Attempts to improve the agreement using the two other possible space-groups were fruitless. Hence, in the absence of any evidence to the contrary, the structure of Ni_4W is that based on $\text{C}_{4h}^5 - \text{I } 4/m$ with $x = 0.400$ and $y = 0.200$.

The structure is such that each atom has twelve nearest neighbors; W has twelve nearest Ni neighbors, and Ni has three nearest W neighbors and nine nearest Ni neighbors. A Ni atom has one W and three Ni neighbors at a distance of 2.5626 Å in the same basal plane, and two W and six Ni neighbors at 2.5377 Å in parallel planes above and below the basal plane.

The mechanism by which Ni_4W forms was studied by determining the sequence of changes in the intensities and positions of the lines in X ray diffraction patterns. Samples were aged for various times at temperatures between 750 and 950°C, after an initial solution treatment and quench from 1150°C.

The X ray photographs of the 19.8 at. pct W alloy in the ordered state for shorter aging times also included lines corresponding to the gamma body-centered cubic phase. In all cases, the intensities of the gamma lines were less in the photograph of the ordered state than in the solution treated state, and decreased further upon longer aging. Thus, the gamma phase, as well as the alpha phase, is involved in the reaction which produces the beta phase.

There are two possible mechanisms by which Ni_4W might form, each having a characteristic sequence of diffraction patterns. In an ordering reaction, "the crystal structure of the alloy changes gradually as time proceeds; the lines of the initial pattern change intensity, become diffuse, split into other lines, and, finally, the new lines move into constant positions and become sharp."⁴ A phase change on the other hand is indicated by a sequence in which "the lines on the initial pattern remain almost unaltered in position and sharpness, but decrease in intensity during the reaction, while new lines appear and increase in intensity without much change in sharpness or position."

* I_{001} does not vary with change in x, y .

At 750°C, for aging times up to 17 hr, the alpha and gamma lines retain their position and intensity, indicating that there is no change in structure. Perhaps longer times at this temperature would have produced appreciable X ray diffraction effects. At 775°C and higher temperatures (800, 850, 900 and 925°C) new lines appear in the diffraction patterns. For shorter aging times, the change in structure is indicated by a blurring of the lines,

and, on further aging, the lines sharpen and move into position and new weak lines appear. This behavior is evidence of a mechanism similar to an ordering reaction as opposed to an ordinary phase change.

At 950°C, however, the initial lines retain their position and sharpness, but decrease in intensity while new lines appear in the pattern in the manner characteristic of a phase change. The final structure obtained at this

temperature by a phase change is the same as that obtained by a different reaction at the lower temperatures. Thus, the mechanism, but not the product, of the reaction appears to depend upon the temperature. Diffraction patterns illustrating the two sequences of changes in the 19.8 at. pct W alloy are given in Fig 3-7.

The X ray diffraction pattern of a quenched and aged sample of the 17.6 at. pct W alloy (17 hr at 1150°C—oil

quenched, and aged 65 hr at 950°C—oil quenched) showed the alpha face-centered cubic phase as well as somewhat diffuse lines of the ordered, body-centered tetragonal structure. Several gamma lines were present in the patterns for shorter aging times, but they decreased in intensity with increased time of aging, indicating that gamma is unstable in the 17.6 at. pct W alloy at 950°C. The beta phase obtained with this sample was not as

perfectly crystalline as that shown by the 19.8 at. pct W alloy for the same heat treatment, confirming the fact that the latter is closer to the stoichiometric ratio of the ordered compound.

Samples of the 17.6 at. pct W alloy were aged at various temperatures below 950°C and examined by X ray diffraction. It was found that samples aged below 850°C consist of only the beta phase, while those aged above this temperature are composed of the

- d. Same sample as Fig 8b, but with oblique light at 1000 X. Beta phase with striations.

alpha phase as well. These results are evidence that the range of solid solubility of the beta phase is wider than reported by Ellinger and Sykes. It appears that the beta region in the constitution diagram should be extended to the left below 850°C to at least 17.6 at. pct W. No data are available to establish the boundary on the right, that is, at W concentrations above 20 at. pct.

The diffraction pattern of a solution treated (17 hr at 1150°C—oil quenched) sample of the 14.1 at. pct W alloy (34.06 pct by weight), showed lines of only the alpha phase with $a_0 = 3.584 \pm 0.001 \text{ \AA}$. This result is in agreement with the boundary drawn by Ellinger and Sykes between the alpha and alpha plus gamma fields.

Aging this alloy for 17 hr at 850°C and at 900°C produced no change in the diffraction pattern, although Ellinger and Sykes found a marked increase in hardness for these heat treatments.

METALLOGRAPHY

The microstructure of the alloys in both the quenched and aged conditions were examined. The 19.8 and 17.6 at. pct W alloys in the quenched state showed an alpha solid solution matrix with spheroids of gamma. The alloy with lower tungsten content had less gamma phase. For the aged condition, the microstructures of these two alloys display a decrease in the amount of gamma and the formation of new areas

in the matrix. There is no difference in the type of microstructure obtained with samples aged at 850 and 950°C. These new areas are no doubt the regions of ordered Ni_4W , since they form where gamma is present. Micrographs of the various structures are shown in Fig 8 and 9.

Ellinger and Sykes report that the microstructure of the 14.1 at. pct W alloy in the quenched condition shows a homogeneous solid solution of alpha. After long aging, there is a thickening of grain boundaries and a general darkening of the alpha grains. These authors conclude from this observation that the alloy has decomposed into two phases. This need not be the case, since the same changes in appearance can occur on ordering.

FIG 9a-c—19.8 atom percent W alloy. Slightly reduced in reproduction.

a. Same heat treatment and phases as Fig 8a.
b. Same heat treatment and phases as Fig 8b.
c. Same heat treatment and phases as Fig 8c.

ELECTRICAL RESISTIVITY

Electrical resistivity measurements were made on the 19.8 and 17.6 at. pct alloys in the solution treated and aged conditions. The results obtained are tabulated below:

Table 2 . . . Results of Electrical Resistivity Measurements

Electrical resistivity at room temperature in microhms per cm

| Atom percent W | Solution Treated* | Aged† |
|----------------|-------------------|-------|
| 19.8 | 110.2 | 54.4 |
| 17.6 | 125.4 | 81.2 |

* 17 hr at 1150°C—oil quenched

† 17 hr at 1150°C—oil quenched

65 hr at 950°C—oil quenched

The sharp drop in electrical resistivity upon aging indicates the migration of atoms to periodically arranged sites in the structure, that is, increasing order. The fact that the resistivity of the 17.6 at. pct W alloy does not drop to as low a value as does the 19.8 at. pct W alloy upon aging at 950°C is

explained either by the fact that the former consists of alpha and beta whereas the latter is entirely beta, or that the 19.8 at. pct W alloy is better ordered, being nearer the stoichiometric ratio Ni_4W .

HARDNESS

The hardness of the 19.8 at. pct alloy as a function of the time and temperature of aging was determined. These results are shown in Fig 10, and it is seen that the hardness of the alloy increases in the usual manner as the time and temperature are increased. There is a definite indication of over-aging at all temperatures, and the time of overaging increases with decreasing temperature. The hardening curves at 850 and 950°C appear to be similar in form, but differ from that obtained at 750°C.

Hardness data obtained by Ellinger and Sykes for an alloy similar to the

17.6 at. pct alloy show much the same behavior except that the maximum hardnesses attained are less than those developed in the 19.8 at. pct W alloy.

It is apparent that Ni_4W may be classified as an intermetallic compound since it has a narrow range of homogeneity, a simple stoichiometric formula, and an ordered structure.⁶ Beta, as formed in these experiments, is characterized by extreme brittleness, high hardness, and relatively high electrical resistivity.

Summary and Conclusions

At approximately 20 at. pct tungsten in the Ni-W system there exists an ordered beta phase which is an intermetallic compound Ni_4W . Its structure is body-centered tetragonal with $a'_0 = 5.730 \pm 0.001\text{\AA}$, $c'_0 = 3.553$

FIG 10—Hardness of 19.8 atom percent W alloy as a function of time and temperature of aging after quenching from 1150°C.

$\pm 0.001\text{\AA}$ and $c/a = 0.620$. The unit cell contains two W atoms at 000 and $\frac{1}{2} \frac{1}{2} \frac{1}{2}$ and eight Ni atoms at 0.100 0.300 0.500; 0.200 0.600 0; 0.300 0.900 0.500; 0.400 0.200 0; 0.600 0.800 0; 0.700 0.100 0.500; 0.800 0.800 0; 0.900 0.700 0.500 (space group C_{4h}^{24} — $I4/m$.)

Beta forms upon prolonged heating below $970 \pm 10^\circ\text{C}$ from an alpha face-centered cubic phase and a gamma body-centered cubic phase. The structure of Ni_4W is based primarily on the alpha face-centered cubic lattice which undergoes a slight tetragonal distortion. The true unit cell, however, has a volume which is 2.5 times the volume of the small tetragonal cell.

The mechanism of formation of Ni_4W appears to be temperature dependent. On the basis of the sequence

of changes in the diffraction patterns, it is concluded that up to quite high temperatures the reaction proceeds by a mechanism similar to ordering but at still higher temperatures occurs by a phase change.

Evidence is presented which shows that the range of solid solubility of the beta phase is wider than reported previously.

The hardness, electrical resistivity, and microstructures of the alloys are discussed.

Acknowledgment

The authors of this paper are indebted to Dr. Roman Smoluchowski for several useful and provocative discussions. It is also a pleasure to

acknowledge the aid given by H. W. Becker, E. T. Asp, and C. Cherry.

Sulphur Equilibria between Iron Blast Furnace Slags and Metal

GERALD G. HATCH* and JOHN CHIPMAN,* Member AIME

ONE of the important functions of the iron blast furnace is the desulphurization of pig iron before it enters the steelmaking furnaces. However, the increasing concentrations of sulphur in the metallurgical coke, source of approximately 90 pct of the sulphur present in the blast furnace charge, and demands for higher rates of production within recent years have increased the need for greater desulphurization within the iron blast furnace. Furnace operators are beginning to look for desulphurizing agents other than blast furnace slag to accomplish the desired degree of desulphurization. A considerable amount of work has been done on desulphurization outside the furnace with soda ash, calcium carbide and various synthetic slags. Whether the desulphurization of pig iron is accomplished wholly inside the furnace or partly inside and the remainder outside, will be determined by the economics involved. Regardless of which is the case, it is believed that it is necessary to have a better understanding of the physical chemistry of desulphurization by blast furnace slags. To this end, it is the object of the present investigation to attempt what is believed to be the first equilibrium study of the distribution of sulphur between liquid pig iron and a wide range of blast furnace slag compositions.

Review of Literature

There is a considerable amount of information in the literature concerning the desulphurizing power of iron blast furnace slags, the solubility of various sulphides in the slags, and the effect on desulphurization of temperature, of elements dissolved in the liquid iron, and of viscosity. However, there is nothing to indicate that the equilibrium distribution of sulphur between liquid iron saturated with carbon and iron blast furnace slags has been studied

experimentally.

Wentrup¹ has made probably the most detailed study of the desulphurization of pig iron to date. He considered that there are three distinct aspects involved, namely: 1. Desulphurization within the blast furnace (by lime and manganese). 2. Subsequent desulphurization by manganese. 3. The effect of subsidiary reactions on the desulphurization by manganese.

The experimental work carried out by Wentrup was devoted mainly to obtaining a better understanding of how desulphurization by manganese was accomplished in the mixer and the ladle. Particular attention was given to the part played by carbon, silicon, and phosphorus associated with manganese in the iron, and the effect of temperature on desulphurization. The experimental results indicated that desulphurization by manganese is purely a process of crystallization of manganese sulphide. The addition of silicon to iron melts containing 3.5 pct carbon and less than 0.5 pct manganese had no noticeable effect on desulphurization, but with 1-2 pct manganese the silicon additions improved the desulphurization. Additions of phosphorus also resulted in improved desulphurization by manganese, but the effect was not as marked as in the case of silicon. It was also found that desulphurization by manganese was further improved by lowering the temperature.

In order to explain desulphurization inside the blast furnace, Wentrup considered the system iron, sulphur, calcium, oxygen, manganese, (silicon). The distribution of sulphur between the metal and slag was represented by the following equation:

The parentheses and the brackets represent the equilibrium concentrations in weight per cent of the slag and metal constituents, respectively.

Since

Substitution of Eq 2, 3, and 4 into Eq 1 resulted in

Eq 5 was used to calculate $\frac{(S)}{[S]}$ and $[S]$ at 1480°C for slags containing 30-50 pct lime, 0.1-2.5 pct iron oxide, 0-26 pct silica, 2 pct sulphur and iron analyzing 1.5 pct manganese. The value for L_{FeS} at 1480°C was found to be equal to 4.5, based on the experimental work of Bardenheuer and Geller.² The results of the calculations are shown in Table I. Although the slags are hypothetical and do not represent the range of compositions found in ordinary blast furnace practice, the calculations indicate that lime is effective in controlling desulphurization only if the iron oxide and silica contents of the slag are kept low. Schenck³ did not claim K_1 to be a true equilibrium constant, but an empirical value which varied with the silica content of the slag.

Holbrook^{5,6} and Joseph studied the desulphurizing power of blast furnace slags. From their experiments carried out under standardized laboratory conditions, desulphurizing power was defined as being equal to the ratio:

$$\frac{\% \text{ sulphur in slag}}{\% \text{ sulphur in metal}} = \frac{(\% \text{ S})}{[\% \text{ S}]}$$

No mechanical method of mixing the slag and metal was employed in this work, as the investigation was not concerned with attainment of equilibrium but with the determination of the relative desulphurizing powers of slags under controlled laboratory conditions. It was found that in magnesia-free slags the desulphurizing power increases rapidly as lime replaces silica; less rapidly as lime replaces alumina and slowly as alumina replaces silica. The desulphurizing power decreases slightly with the addition of magnesia to the acidic slags and increases markedly when magnesia is added to the very basic slags. Magnesia decreases the viscosity of the slags, and thereby allows the very basic slags to exhibit their inherently strong desulphurizing qualities. Holbrook and Joseph also suggested that the evolution of carbon monoxide accompanying desulphurization retards the descent of falling metal drops and carries calcium sulphide and globules of metal away from the bath interface and into the slag, contributing to the effectiveness of the reaction.

McCaffrey and Oesterle⁷ have carried out comprehensive experiments on the solubility of calcium sulphide and manganese sulphide in slags of the ternary system, silica, lime, and alumina. Their results indicate that the solubility limit of sulphur as calcium sulphide and manganese sulphide is considerably higher than the sulphur content of ordinary blast furnace slags, and that the actual chemical composition of the slag is of less importance than the temperature of the slag in affecting sulphur solubility.

Imhoff⁹ has claimed that sulphur occurs in three forms in blast furnace slags: (1) combined as calcium sulphide; (2) free sulphur held in solution in the slag and (3) sublimed sulphur, the result of excess sulphur in the burden.

Martin, Glockler, and Wood¹⁰ examined in the laboratory the forms in which ferrous sulphide, manganese sulphide, and calcium sulphide occur in a blast furnace slag. The glasses obtained by quenching a molten slag to which the sulphides were added separately, were shown to contain a colloidal phase. The data indicated that the sulphides are present also in solution in the slag. The authors believed that the colloidal particles were sulphides and that the colloidal condition was present in the molten slag, as heat treatment below the softening point did not affect the intensity of the colloid. In order to explain the stability of the colloidal phase in molten slags Martin and Glockler proposed an ionic constitution for blast furnace slags.

The work by Martin and Derge¹⁶ on the electrical conductivity of molten blast furnace slags has provided further evidence of high degrees of ionization. Herasymenko¹⁷ has proposed that molten slags are completely ionized.

In contrast to the ionization concept has been the older molecular theory of blast furnace constitution. The researches of McCaffrey,¹¹ Field and Royster,⁸ Hay¹² and others on the viscosity of mixtures of lime, silica, alumina, and magnesia at temperatures well above their melting points, show that the slags behave in a manner similar to simple solutions, the changes in viscosity with change of composition being relatively small. However, McCaffrey,¹³ and Colclough¹⁴ have stated that in the temperature range 50–100°C above the melting range blast furnace slags are composed of minerals of definite composition and properties.

Abell¹⁵ also was convinced that molten blast furnace slags are composed of molecular compounds. However, he proposed that the slags are composed of spinels and silicates and maintained that the silicates act as comparatively inert solvents for the spinels which alone are capable of reacting with the sulphur in the iron.

Experimental Method

FURNACE

In order to study the equilibrium distribution of sulphur between iron blast furnace slags and liquid iron saturated with carbon, a small induction furnace was built, which held a graphite crucible containing 200 g of metal and 400 g of slag. The amount of metal was determined by the maximum number of samples that would be required in any run. The comparatively large amount of slag was believed to be sufficient to maintain the slag at constant composition over the narrow temperature range employed.

Carbon monoxide gas is evolved in the desulphurization reaction. If an equilibrium state was to be maintained, the partial pressure of this gas had to be held constant. Thus carbon monoxide was used as the furnace atmosphere. Since the crucible was to be made of graphite, little or no stirring of the metal could be expected from electro-magnetic forces. Thus it was proposed to attain the equilibrium state by stirring the slag and metal with a graphite stirring rod.

The induction furnace is shown in Fig 1. The graphite crucible, *M*, is 7 in. long and 2¼ in. id with a wall thickness of ⅜ in., and it contains a well, 1 in. in diam and ¼ in. in depth, which provides an additional depth of metal for sampling. The crucible is insulated on all sides by a porous carbon tube, *K*, and by porous carbon blocks, *L* and *P*. Lampblack is packed between the porous carbon tube and the silica tube, *I*, to further insulate the furnace. The silica tube is placed in an annular slot, fitted with a silicone gasket, on the soapstone base.

A water-cooled brass plate, *C*, closes off the top end of the silica tube. The brass plate is fitted with a rubber gasket. Three holes were drilled in the plate to serve as inlets for taking samples and temperature measurements, for inserting the graphite stirring rod and the graphite tube containing the carbon monoxide gas.

The graphite stirring thimble is threaded into the stirring rod, which is attached to the chuck of a $\frac{1}{6}$ hp variable speed electric motor. Carbon monoxide gas contained in a high pressure cylinder is passed first through a precision bore rotameter tube, before entering the furnace by means of a graphite tube. This graphite tube is $\frac{1}{8}$ in. id and 21 in. long with a $\frac{3}{16}$ in. wall thickness. The tube rests on the furnace bottom, thus causing the gas to flow through both the metal and slag layers. Both the stirring rod and graphite tube are fitted with brass bushings which rest on the brass plate. The furnace is thus closed to the atmosphere at all points except for the sampling-temperature measuring hole. This insures that all the carbon monoxide is withdrawn from the furnace and burned at one point.

METAL AND SLAG CHARGES

High-carbon wash metal was used as the source of iron. When it was desired to approach equilibrium from the side of high sulphur in the metal, ferrous sulphide was added to the metal. In order to approach equilibrium from the slag side a low sulphur melting stock was prepared, which consisted of electrolytic iron melted in contact with a graphite rod, and calcium sulphide was used as the source of sulphur in the slag. In those runs in which the silica content of the slag was high, silicon metal was added to the metal charges to decrease the amount of transfer of silicon from slag to metal. In order to homogenize the slags as much as possible before using them in the experimental furnace, a series of eight master slags were melted in graphite crucibles. These master slags were made up from mixtures of chemically pure lime, purified silica sand, alumina, and magnesia. They were crushed, sampled, and analyzed. Slag charges for the experimental runs were readily prepared from the master slags, with small additions of the pure constituents as required to produce slags of the desired analyses.

TEMPERATURE MEASUREMENT

In the first run, the temperature was measured with both an optical pyrometer and a platinum-platinum, 10 pct rhodium thermocouple. The optical pyrometer was sighted down a $\frac{1}{2}$ in. id graphite tube, which had its lower end closed off. The readings taken with the thermocouple inside

FIG 1—Details of furnace.

the graphite tube checked within $\pm 2^\circ\text{C}$ at 1500°C with those taken simultaneously with the optical pyrometer. Thus, since the true black body temperature was obtained with the optical pyrometer, and as the temperature was so readily measured this way, the optical pyrometer was used exclusively in all subsequent runs. The platinum-platinum, rhodium thermocouple served to check the optical pyrometer periodically. The main source of error with respect to temperature was not in the measurement but in the difficulty of maintaining the temperature constant by means of the manually operated power supply. It was found that the temperature could be held only within $\pm 10^\circ\text{C}$ of the desired value for the duration of each run.

FURNACE OPERATION

From the experience gained in the early runs the following procedure was

found to be satisfactory in establishing equilibrium:

Two hundred grams of wash metal were charged into the crucible. With the stirring rod resting on the metal charge, the graphite cover, the porous carbon insulating block and the brass plate were placed in position. Four hundred grams of slag of the desired composition and having 1.5 pct sulphur as calcium sulphide were then introduced into the crucible by means of a funneled pyrex tube. The water and power were turned on and the furnace was purged out with nitrogen. After the charge was melted, the stirring mechanism was clamped so that the bottom of the stirring thimble was $\frac{1}{8}$ of an inch from the bottom of the crucible. The stirrer was started and operated at 500 rpm. The nitrogen gas was turned off and carbon monoxide was introduced, at approximately 900 ml per min., down into the melt by means of the graphite tube which rested on the furnace bottom. A pilot

flame was maintained at the mouth of the sampling hole to insure that the carbon monoxide burned as it was discharged from the furnace. In case any carbon monoxide escaped unburned, an exhaust hood was placed close to the furnace.

The temperature was adjusted to the desired value and maintained at that value for the duration of each run by adjusting the power input. Experience with various slags indicated that the sulphur equilibrium was attained in 4 to 6 hr time, depending on the viscosity, temperature, and composition of the slag. As a result, the duration of the runs was established at 7 hr. Metal samples were taken at end of 5, 6, and 7 hr. The metal sampler consisted of thin-walled silica tube, $\frac{3}{16}$ in. id, attached to a rubber aspirator bulb. No real difficulty was experienced in obtaining sound 10 to 15 g samples provided the slag was not too viscous. The slag was sampled at the end of the run by dipping a $\frac{5}{8}$ in. diam brass rod into the slag layer. The last metal sample was analyzed for sulphur, carbon, and silicon, while the first and second samples were analyzed for sulphur only. A complete analysis was made on the slag sample. Both the metal and slag samples were analyzed for sulphur by the combustion method. This method consists of igniting the sample at 1300 to 1400°C in a stream of oxygen. The gas given off from the sample is bubbled into a 3 pct solution of hydrochloric acid and titrated as it is evolved with potassium iodate solution. The combustion method takes less sample, 1 g of metal or 0.2 g of slag, than either the volumetric or gravimetric method. It is more accurate than the volumetric and is much less tedious to perform than the gravimetric. The sulphur determinations on the metal samples by this method are accurate within ± 0.001 pct sulphur. An analysis is completed in less than 10 min. time.

SLAG VISCOSITY AND SLAG-TO-METAL TRANSFER OF SILICON

At temperatures above 1500°C, a few preliminary runs demonstrated that in a graphite crucible liquid iron could absorb as much as 10 pct silicon from a slag containing more than 40 pct silica. Since the effect of such high percentages of silicon on the equilibrium con-

centration of sulphur has not been determined experimentally, it was planned to maintain the silicon content in the metal at less than 2 pct. In order to do this, the maximum allowable concentration of silica in the slag was estimated to be 35 pct, with a maximum temperature of 1500°C. On the other hand, since the viscosity of slags increases with decrease in temperature, for any given slag there is a temperature below which it is not feasible to carry out any equilibrium studies. The work by McCaffrey on viscosity measurements of blast furnace slags proved invaluable in determining this lower temperature limit. From McCaffrey's data and from the experience gained in the first seven runs it was found that 1400°C was about the lowest temperature at which an appreciable range of slag compositions could be investigated.

On the basis of the above considerations, a series of runs was made at 1425°C in order to determine the relationship between slag composition and desulphurization. Runs were also made at 1500°C to study the effect of temperature on desulphurization.

In runs H-31 and H-37 the silicon concentrations in the metal were 3.23 and 4.80 pct, respectively. These higher silicon concentrations did not appear to affect the sulphur equilibrium. In addition, calculations by Chipman on the activities of liquid iron in the iron-silicon-carbon system indicated that the activity of iron is only slightly affected by additions of up to 10 pct silicon to liquid iron saturated with carbon. Also, the work of Wentrup on the desulphurization of pig iron by manganese showed that silicon did not affect desulphurization provided that the manganese concentration was less than 0.5 pct. On the basis of these facts it was assumed that silicon does not greatly affect the sulphur equilibrium concentration in liquid iron saturated with carbon.

Although the present investigation was concerned primarily with the equilibrium distribution of sulphur between slag and metal it was interesting to determine whether an equilibrium was established with respect to silicon. It was found that the silicon equilibrium was much more slowly attained than was the sulphur equilibrium between slag and metal. This fact was demonstrated when runs H-19, H-24, H-25, and H-36 were remelted and more sulphur was added in order to study the effect of an increase in the sulphur content of the slags on the sulphur

equilibrium. In these remelted runs, it was observed that the silicon concentrations in the metal were higher than they had been in the original runs, showing that equilibrium with respect to silicon had not been originally attained. It was interesting to note that in the original runs, even though the silicon equilibrium was not attained, lowering the temperature from 1550 to 1425°C caused the silicon slag-to-metal transfer to reverse, and hence resulted in a decrease in the silicon content of the metal. This indicated that the temperature coefficient for the silicon equilibrium is very high.

In run H-33, the silicon equilibrium was approached from both sides by first holding the temperature at 1500°C for 6 hr, followed by 1 hr at 1600°C and then $3\frac{1}{2}$ hr at 1500°C. The equilibrium state was found to lie between 1.71 and 2.29 pct silicon in the metal. This run was remelted and maintained at 1500°C for another 7 hr. At the end of this period the metal analyzed 2.08 pct silicon. On the basis of these results, the remelted runs H-34, and H-44 to H-48, are considered to have approximated equilibrium with respect to silicon.

ATTAINMENT OF THE SULPHUR EQUILIBRIUM

Ferrous sulphide was the only source of sulphur available in the early runs. Consequently at the beginning of each run the slag-metal system was far removed from equilibrium and the initial sulphur transfer to the slag was extremely rapid as was evidenced by the strong bubbling of the slag and the evolution of carbon monoxide gas. However, the bubbling action soon stopped and the rate of sulphur transfer proceeded extremely slowly thereafter, so slowly that the sulphur content of the metal had not reached a constant value after 5 hr with a stirrer speed of 100 rpm. In order to improve the possibility of attaining equilibrium within a reasonable length of time, the speed of the stirring rod was increased to 500 rpm in run H-8. However, the increased stirring speed did not greatly improve the rate of attaining equilibrium.

Since the equilibrium concentrations of sulphur in the metal for the various slags studied appeared to be quite low it was believed that the equilibrium state might be more readily approached from the side of high sulphur in the slag. In runs H-9 and H-14, sulphur, as calcium sulphide, was added to the slag charge. The sulphur reached a con-

stant value after 4 and 2 hr in runs H-9 and H-14, respectively. This difference in the time required to reach equilibrium was occasioned by (1) temperature, run H-9 being at 1425°C and H-14 at 1500°C, and (2) slag composition, the slag used in run H-14 being much more basic than in run H-9.

In an effort to further decrease the time to equilibrium carbon monoxide was bubbled into the metal and slag at approximately 600 ml per min. in run H-17. Thus with calcium sulphide as the source of sulphur, with the stirrer operating at 500 rpm and with carbon monoxide bubbling through the bath, it appeared that 4 or 5 hr was sufficient time for any slag to come to equilibrium with the metal. Consequently, in run H-19 the temperature was held constant at 1500°C for 5 hr and then it was decreased to 1425°C where it was maintained for 4 hr. This procedure was adhered to from run H-19 to H-30, except where viscosity and silicon-transfer considerations did not permit the slag to be studied at both 1500 and 1425°C.

The results of the analyses on these runs showed that the sulphur content of the metal increased when the temperature was lowered from 1500 to 1425°C. However, the analyses also revealed that equilibrium had not been attained in all these runs. Thus, beginning with run H-31, the furnace was held at one temperature for 7 hr and the rate of flow of carbon monoxide was increased from 600 to 900 ml per min. This practice insured the attainment of equilibrium, and was followed in all the succeeding runs.

It must be pointed out that in every run in which calcium sulphide was used as the source of sulphur, the successive metal samples did not increase in sulphur, but rather decreased, until the equilibrium concentration was obtained. A typical example of this fact is shown in Fig 2. This was true even when electrolytic iron which contained less than the equilibrium concentration of sulphur was used. The high sulphur content of the first metal samples was probably due to the calcium sulphate present in the calcium sulphide charged into the crucible.

The plot of per cent sulphur in the metal against the time sampled, shown in Fig 3, demonstrates that the sulphur equilibrium can be approached from the slag side. Calcium sulphide was the source of sulphur in this run. The temperature was maintained at 1425°C for 6 hr so as to allow the transfer of

FIG 2—Typical determination of equilibrium at 1500°C.

FIG 3—Equilibrium approached from slag and metal sides.

sulphur from the metal to the slag until equilibrium was attained. The temperature then was increased to 1550°C and held constant for 3 hr, in order to decrease further the sulphur concentration of the metal. Nitrogen gas was bubbled through the melt during this period to aid in the metal-to-slag transfer of sulphur. At the end of the 3 hr period, the temperature was lowered again to 1425°C and maintained for 6 more hours. The sulphur content returned to its former value corresponding to equilibrium at this temperature.

SULPHUR CONTENT OF THE SLAGS

The slags in most of the first 38 runs analyzed 1.5 pct sulphur. This percentage of sulphur in the slag resulted in very low sulphur concentrations in the metal, especially with the more basic slags. Thus it was believed desirable to increase the sulphur concentration in the slags in order to increase the sulphur content of the

metal, and thereby improve the accuracy of the sulphur determinations on the metal samples. Nine of the original runs were remelted and iron sulphide was added in quantities to give approximately 2.5 pct sulphur in the slags. Examination of the analytical results for these runs indicated that the sulphur concentration in the metal did not increase proportionally to the increase of sulphur in the slag. As a result, three runs were made with slags containing approximately 5 pct sulphur. Although the percentages of sulphur found in the metal samples for these runs were higher than would occur with similar slags containing 1.5 pct sulphur, they were much lower than would be the case if the sulphur in the metal was proportional to the sulphur in the slag.

IRON CONTENT OF THE SLAGS

Iron is probably present in blast furnace slags as iron oxide, iron sulphide and as metallic iron. Although it is known that the concentration of

iron is low in blast furnace slags, it was believed to be advantageous to determine the quantity of combined iron present in the slags studied in the present investigation. The mixing of the slag and metal by the graphite stirring rod caused iron to be dispersed throughout the slag. As a result, even though the slag was allowed to stand for at least one minute before being sampled, tiny droplets of iron were present in the slag samples. This magnetic iron was separated roughly by means of a magnet. The concentration of iron remaining after this separation was found to be 0.2 to 0.5 pct, reported as iron oxide (Table 3). In order to determine the degree to which the simple magnet had removed the metallic iron, several slag samples were passed over a Franz iso-dynamic separator. These slag samples included slags containing 1.5, 2.5, and 5.0 pct sulphur. The samples were passed over the separator until their iron contents became as nearly constant as could be detected by the colorimetric method used for chemical analysis. The results of these analyses are shown in Table 2 where the iron is reported as iron oxide. These figures do not give a true value for iron oxide as they include any iron sulphide present in the slag, but they provide a good indication of the amounts of chemically combined iron in blast furnace slags at equilibrium with liquid iron saturated with carbon. The iron content did not appear to be related to the sulphur concentration in the slag.

Results

The results of chemical analyses of the slag and metal samples for the equilibrium runs are shown in Table 3. The only significant sources of error from chemical analysis occurred in the analytical results obtained for sulphur in the metal. Eight metal samples that had been analyzed for sulphur were re-labeled and submitted for analysis

*FeO after incomplete magnetic separation. Compare Table 2 showing results after repeated magnetic treatment.

again. The two sets of results differed in all but one case, by not more than 0.001 pct sulphur. (Table 4.) However, the desulphurization ratio, $\frac{(S)}{[S]}$, weight per cent of sulphur in the slag divided by weight per cent of sulphur in the metal, can be considerably affected by even this small change in the sulphur content of the metal. A comparison of run H-19 with H-44 illustrates this point. Run H-44 was a remelt of run H-19 to which more sulphur as iron sulphide had been added.

| | (S) | 1st Analysis | | 2nd Analysis | |
|---------|------|--------------|-------------------|--------------|-------------------|
| | | [S] | $\frac{(S)}{[S]}$ | [S] | $\frac{(S)}{[S]}$ |
| H M 19d | 1.59 | 0.006 | 265 | 0.005 | 318 |
| H M 44c | 2.25 | 0.006 | 375 | 0.007 | 322 |

These figures demonstrate the difficulties involved not only in correlating the desulphurization ratio with slag composition, with the more basic slags, at a constant sulphur concentration in the slag, but also in determining whether or not the sulphur in the metal is directly related to the sulphur in the slag.

EFFECT OF SLAG COMPOSITION ON DESULPHURIZATION

Since the majority of the runs were made at 1500°C with slags containing 1.5 pct sulphur, it was believed that a relationship between desulphurization and slag composition could best be established from the data collected in these runs. Desulphurization of pig iron is known to depend on the basicity of the slag; thus there was the possibility that the desulphurization ratio, $\frac{(S)}{[S]}$, might be simply related to an index of basicity.

All slag analyses were converted to mols per 100 g of slag. In the chemical analysis of the slags all the calcium present was reported as lime. Any calcium present in the form of calcium sulphide was included in the total molar concentration of lime and was, therefore, considered to act as a base.

Plots were made of the desulphurization ratio versus the molar ratios

$\frac{\text{CaO}}{\text{SiO}_2}$, $\frac{\text{CaO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$, $\frac{\text{CaO} + \text{MgO}}{\text{SiO}_2}$, and $\frac{\text{CaO} + \text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$, respectively. Of these plots the one of $\frac{(\text{S})}{[\text{S}]}$ versus $\frac{\text{CaO} + \text{MgO}}{\text{Al}_2\text{O}_3 + \text{SiO}_2}$

(Fig 4) gave by far the best correlation in relating the desulphurization ratio to basicity. In this plot it was noted that all but one of the points below the line represent slags containing more than 6 pct magnesia, while all but one of the points above the line represent slags containing less than 6 pct magnesia. This fact indicated that magnesia is not as effective a desulphurizing agent as lime. The substitution of various factors for K in the basicity ratio $\frac{\text{CaO} + K \cdot \text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$ showed that the factor of $\frac{2}{3}$ resulted in the closest correlation of the points representing slags with high and low magnesia concentrations. (Fig 5)

It can be said that the relating $\frac{(\text{S})}{[\text{S}]}$

to a basicity ratio, a good correlation of the data might be obtained by the use of factors for any or all of the four constituents lime, magnesia, silica, and alumina. Thus it was believed that a more quantitative relationship might be developed if the desulphurization ratio could be expressed as some function of excess base, in a manner analogous to that employed by Grant and Chipman⁴ in their study of sulphur equilibrium between liquid iron and basic open hearth slags. Since blast furnace slags are considered to consist mainly of bisilicates, it was first assumed that 1 mol of acid neutralized 1 mol of base, that 1 mol of magnesia was equivalent to 1 mol of lime, and that 1 mol of alumina was as effective as 1 mol of silica. Excess base thus became equal to BASES $(\text{CaO} + \text{MgO}) - \text{ACIDS } (\text{SiO}_2 + \text{Al}_2\text{O}_3)$. A graph of the desulphurization ratio versus this expression for excess base (Fig 6) produced a scattering of the points comparable to that obtained when the

ratio $\frac{\text{CaO} + \text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$ was employed as

FIG 4—Effect of $\frac{\text{CaO} + \text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$ on desulphurization at 1500°C.

FIG 5—Effect of basicity on desulphurization at 1500°C.

FIG 6—Effect of $(\text{CaO} + \text{MgO}) - (\text{SiO}_2 + \text{Al}_2\text{O}_3)$ on desulphurization at 1500°C.

FIG 7—Effect of excess base on desulphurization at 1500°C.

FIG 8—Relationship between basicity and desulphurization at 1500°C for 1.5 to 5 pct sulphur slags.

FIG 9—Effect of temperature on desulphurization.

the abscissa (Fig 4).

In order to improve the correlation between the desulphurization ratio and excess base, it was assumed that 1 mol of magnesia was equivalent to only $\frac{2}{3}$ of a mol of lime, that is, $1\frac{1}{2}$ mols of magnesia were equal to 1 mol of base, and the other assumptions were considered to remain the same as before. Excess base was then defined as being equal to $(\text{CaO} + \frac{2}{3}\text{MgO}) - (\text{SiO}_2 + \text{Al}_2\text{O}_3)$. The variation of the sulphur distribution ratio with this expression for excess base is shown in Fig 7. Considering the accuracy of the data this graph represents a very good correlation.

It was expected that the relationships developed for the 1.5 pct sulphur slags would correlate the data for all the slags at 1500°C irrespective of their sulphur content. However, in the plot of $\frac{(S)}{[S]}$ versus $\frac{\text{CaO} + \frac{2}{3}\text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$ for slags containing 1.5, 2.5, and 5.0 pct sulphur three curves were obtained as shown in Fig 8. This was also true for the plot of $\frac{(S)}{[S]}$ versus excess base,

Fig 7. These curves indicate that an increase in the sulphur concentration of the slag does not result in a proportional increase in the sulphur content of the metal, within the range of slag compositions studied. This phenomenon cannot be readily explained with the present data.

EFFECT OF TEMPERATURE ON DESULPHURIZATION

Fig 9 shows the effect on the desulphurization ratio of decreasing the temperature from 1500 to 1425°C. Because magnesia was shown to be two-thirds the equivalent of lime on a molar basis, it is approximately equivalent to lime on a weight per cent basis. Thus from the two curves in Fig 9 it was possible to plot on a ternary diagram iso-sulphur lines at 1500°C and 1425°C, the coordinates being weight per cent $\text{MgO} + \text{CaO}$, SiO_2 , and Al_2O_3 , as shown in Fig 10. This diagram summarizes the effect of slag composition and temperature on the equilibrium sulphur concentrations in liquid pig iron. Although the sulphur concentrations plotted in Fig 10 were obtained for slags containing 1.5 pct sulphur, on the basis of the observations made with slags of higher sulphur content, these concentrations can be regarded as apply-

FIG 10—Metal iso-sulphur lines for 1.5 pct sulphur slags at 1500°C and 1425°C. (Slag composition in weight per cent.)

ing to slags analyzing 1.25–2.00 pct sulphur.

Discussion of Results

Although the basicity ratio

$$\frac{\text{CaO} + \frac{2}{3}\text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$$

correlated the data for the 1.5 pct slags, the expression developed for excess base, $(\text{CaO} + \frac{2}{3}\text{MgO}) - (\text{SiO}_2 + \text{Al}_2\text{O}_3)$ in mols per 100 g of slag, is considered to offer a better means of interpreting the results, as it provides a more direct measure of the effective concentrations of the basic constituents present in the slags. Some of the acid slags contained excess acid according to this expression, but this does not necessarily mean that there is “free” acid present, but rather that alumina, because of its amphoteric nature probably acts partly as a base and only partly as an acid. The tendency of alumina to behave as a base is well demonstrated in Fig 7 by the marked decrease in the slope of the curve in the region representing the more acid slags. With alumina considered as acting partly as a base, a

recalculated value for excess base would increase the slope of the curve in this region. From these observations it can be concluded that alumina acts like silica, on a molar basis, in reducing the desulphurizing power of a basic slag; in the more acid slags it is less harmful than silica.

It was observed that three of the very basic slags (47 to 50 pct lime) disintegrated into a fine powder on solidification. This behavior is a well known characteristic of calcium orthosilicate. Thus it appears that these basic slags contain appreciable quantities of calcium orthosilicate, and therefore, that more than 1 mol of lime has been used to neutralize 1 mol of silica. If this is true, the basic slags contain smaller quantities of excess base than described by the expression $(\text{CaO} + \frac{2}{3}\text{MgO}) - (\text{SiO}_2 + \text{Al}_2\text{O}_3)$.

Thus with alumina acting partly as a base in the more acid slags and with the basic slags containing appreciable quantities of calcium orthosilicate a true graph of the desulphurization ratio versus excess base would have a much steeper slope than occurs with the present expression for excess base.

If sulphur is present in blast furnace

slags mainly in the form of calcium sulphide, then desulphurization can be described by the following reaction:

$$K_1 = \frac{a_{\text{CaS}} \cdot a_{\text{Fe}} \cdot p_{\text{CO}}}{a_{\text{FeS}} \cdot a_{\text{C}} \cdot a_{\text{CaO}_f}}$$

(CaO_f) represents the free or uncombined lime in the slag. An approximate value for the equilibrium constant K_1 at 1500°F can be calculated from the reactions:

Eq 2 was derived from the work of Bardenheuer and Geller² on the distribution of sulphur between liquid iron and iron oxide slag. The expression for the standard free energy of reaction [3] as a function of temperature was developed from the calculations made by Darken and Larsen¹⁹ on Bardenheuer and Geller's data for sulphur equilibria between lime-iron oxide slags and liquid iron. Eq 4 was obtained from Chipman's²¹ tabulations of the

free energy of formation of liquid iron oxide and carbon monoxide at steel-making temperatures.

Addition of Eq 2, 3, and 4 results in $\text{FeS} + (\text{CaO}_f) + \text{C}(gr)$

therefore,

$$K_1 = 3.39 \times 10^4 \text{ at } 1500^\circ\text{C}$$

Since the reaction is endothermic, the equilibrium transfer of sulphur to the slag increases with an increase in temperature, as observed in the experiments.

Under the conditions set up for the experimental work the activity of both the carbon dissolved in the iron and the carbon monoxide gas was equal to unity, the standard states for these two substances being graphite and 1 atm pressure, respectively. The activity of liquid iron was also constant at approximately 0.55 at 1500°C , as determined from Chipman's¹⁸ thermodynamic calculations on the iron-silicon-carbon system. Assuming that activity is proportional to mol fraction for calcium sulphide, iron sulphide and lime, as was done in the determination of the constant K_1 and where N_s and N_m are the number of mols per 100 g of slag and metal, respectively, Eq 1 is transformed to

$$K_1 = 3.39 \times 10^4 = 0.55$$

$$\times \frac{(\text{mols CaS}) \times N_s \times N_m}{N_s \times \text{mols} [\text{FeS}] \times (\text{mols CaO}_f)} = 0.55 \times \frac{(\% \text{ S}) \times N_m}{[\% \text{ S}] \times (\text{CaO}_f)}$$

but since N_m is essentially constant and equal to 2.1, then at 1500°C

$$2.94 \times 10^4 = \frac{(\% \text{ S})}{[\% \text{ S}]} \times \frac{1}{(\text{CaO}_f)} \quad [6]$$

According to Eq 6 the desulphurization ratio $\frac{(\text{S})}{[\text{S}]}$ is proportional to the number of mols of free lime per 100 g of slag. This is in agreement with what was observed when $\frac{(\text{S})}{[\text{S}]}$ was plotted against mols of excess base for a given sulphur concentration in the slags. However, the slope of the curve $\frac{(\text{S})}{[\text{S}]}$ versus excess base for the 1.5 pct sulphur slags at 1500°C was only equal to 560, compared with 2.9×10^4 for the slope of the curve $\frac{(\text{S})}{[\text{S}]}$ versus free lime, as given by Eq 6. Thus the large value calculated for K_1 provides further evidence that the expression $(\text{CaO} + \frac{2}{3}\text{MgO}) - (\text{Al}_2\text{O}_3 + \text{SiO}_2)$ does not give a true value for the excess base, the actual excess being somewhat smaller.

Previously, in discussing the relationship between desulphurization and slag composition, it has been assumed that molten slags are composed of molecular compounds and their constituent oxides. However, the expression of slag composition in terms of excess base can be used equally well whether slags are composed of ions or of molecules. In the ionization theory the basic oxides produce oxygen ions which are absorbed by silica and alumina to form complex ions of the form $(\text{Si}_2\text{O}_7)^{-6}$, $(\text{SiO}_4)^{-4}$, $(\text{Al}_2\text{O}_5)^{-4}$. As the basic oxides replace the acid oxides the oxygen ion concentration increases.

The conclusions previously reached regarding the amphoteric properties of alumina in blast furnace slags can be stated in terms of the ionization theory by the following series of steps representing the transition from acidic to basic solutions, each step requiring the addition of oxide ions:

The presence of calcium orthosilicate in the basic slags is shown by the formation of the stable orthosilicate ion SiO_4^{4-} from the metasilicate ion in a similar series.

The concept of ionization also explains the fact that 1 mol of magnesia was not found to be equivalent to 1 mol of lime. The binding forces between magnesium and oxygen ions are greater than those between calcium and oxygen ions.²⁰ Hence the substitution of 1 mol of magnesia for 1 mol of lime in a slag would result in a decrease in the oxygen ion concentration of the slag. This means that magnesia is not as active a base as lime, and therefore, not equivalent to lime on a molar basis.

Thus, either the molecular or the ionic theories can be employed in explaining the behavior of the various slag constituents. However, blast furnace slags involve such complicated chemical systems that fundamental knowledge is as yet inadequate for the quantitative determination of their properties in the molten state, and therefore it is impossible at present to determine the true value for excess base. This does not mean that the expression $(\text{CaO} + \frac{2}{3}\text{MgO}) - (\text{SiO}_2 + \text{Al}_2\text{O}_3)$ has no real significance. The equilibrium desulphurization ratios for slags containing about 1.5 pct sulphur have been well correlated with this expression for excess base. The result

is shown in the ternary diagram (Fig 10), which allows the equilibrium values of sulphur in the metal to be determined for blast furnace slags at 1500°C and 1425°C .

Since none of the slags studied contained any manganese oxide, it would be of considerable interest to study under equilibrium conditions the effect on desulphurization of manganese oxide in the slag. Also, in order to better understand the constitution of molten slags, activity measurements should be made of simple binary slag systems. These studies can be made by means of either reversible electromotive force measurements, as described by Chang and Derge²² or by slag-metal equilibrium investigations.

PRACTICAL CONSIDERATIONS

The present investigation has shown that the equilibrium sulphur concentrations in the metal are considerably lower than those found in practice. Hence, the problem of attaining better desulphurization with blast furnace slags is controlled by the kinetics and not by the thermodynamics of the metal-to-slag transfer of sulphur. It is important that investigations be carried out to determine the mechanism by which desulphurization takes place, in the manner initiated by Chang and Goldman.²³ Of more immediate significance to blast furnace operators would be a study of the desulphurization attained by various methods of mixing slag and metal. It should not be concluded that such an investigation is not warranted because the time required to reach equilibrium was so great in the present study. A simple process of pouring the metal through the slag might well show that considerable quantities of sulphur can be removed by taking advantage of the inherently strong desulphurizing powers of commercial slags without resorting to other desulphurizing agents.

Summary

From the 57 runs made in the experimental furnace covering a range of slag compositions, consisting of 30 to 50 pct lime, 29 to 40 pct silica, 1 to 19 pct magnesia and 6 to 27 pct alumina at 1500°C and 1425°C , the following conclusions have been reached:

1. The sulphur concentrations in pig iron at equilibrium with blast furnace slags are considerably lower than those found in practice.

2. The desulphurization ratio, $\frac{(S)}{[S]}$,

for slags containing approximately 1.5 pct sulphur is controlled by excess base, where excess base is equal to $(CaO + \frac{2}{3}MgO) - (SiO_2 + Al_2O_3)$ in mols per 100 g of slag.

3. The effect of lowering the temperature from 1500°C to 1425°C is to increase the equilibrium sulphur concentration in the metal. This increase amounted to 0.001 to 0.004 pct in metal containing 0.005 to 0.020 pct sulphur.

4. Magnesia is only two-thirds the equivalent of lime as a desulphurizing agent on a molar basis, or approximately equal on a weight basis.

5. Alumina acts like silica in reducing the desulphurizing power of a basic slag; in the more acid slags it is less harmful than silica.

6. The sulphur concentration in the metal is not directly proportional to the sulphur in the slag.

Acknowledgments

The authors wish to express their thanks to Mr. Donald L. Guernsey and his associates for making the large number of chemical analyses involved. They also wish to thank the Republic Steel Corporation for its generous support of this investigation.

The Beryllium-iron System*

R. J. TEITEL† and MORRIS COHEN,‡ Member AIME

Introduction

THERE is considerable interest in beryllium because of its low density (1.84 g per cu cm), high modulus of elasticity (40×10^6 psi), high melting point (1280°C), and special nuclear characteristics. Moreover, it has fair resistance to corrosion and oxidation. However, the purest beryllium known to the authors is relatively brittle at room temperature, and cannot be fabricated readily. The search for improved properties leads naturally to investigations of beryllium alloys and the phase relationships upon which they are based.

The present paper is concerned with the alloys of beryllium and iron, primarily from the standpoint of the equilibrium diagram. Iron was selected (1) because of its all-round importance in metallurgy, and (2) because the beryllium-iron system is known to be quite complex.

The most recent diagram in the literature is that of Gaev and Sokolov,¹ and covers only the iron-rich end up to 16 wt pct beryllium. Beryllium markedly restricts the austenitic field, closing the gamma loop at about 0.4 wt pct (3 at. pct). On the other hand, beryllium is soluble in α -ferrite up to a maximum of 7.5 wt pct (34 at. pct) at the eutectic temperature of 1160°C. The eutectic composition lies at 10 wt pct beryllium (42 at. pct) and corresponds to a mixture of α and FeBe₂ (called β in the present paper). The solid solubility of beryllium in the α phase decreases with decreasing temperature, and makes precipitation-hardening possible. These findings substantiate the earlier work of Oesterheld,² Wever and Mueller³ and Laissus.⁴

In addition to the FeBe₂ (β) mentioned above, Misch⁵ has reported on

FeBe₅, and indicated evidence for another compound containing still more beryllium.

A preliminary diagram by Gordon,⁶ not hitherto published, is given in Fig 1. Besides the phases previously named, there are shown a solid solution of extended range (ϵ), a compound of limited solubility (ζ), and a high temperature phase (η). Beryllium is designated as θ . The ϵ field contains the

compound composition FeBe₅, and the ζ phase undoubtedly corresponds to the beryllium-rich compound found by Misch.⁵ The region around the ζ phase was proposed by R. J. Teitel based on Gordon's data. The details of the diagram are self-explanatory. It was the unusual complexity of this system that prompted the authors to undertake the present studies. By the same token, more emphasis was placed on the beryllium-rich than the iron-rich end of the diagram.

Experimental Details

RAW MATERIALS

The beryllium employed in this investigation was one of the purest grades available. Its chemical analysis after vacuum melting is given in Table 1. The metal assayed 99.4 wt pct beryllium.

Vacuum melted electrolytic iron of purity shown in Table 1 was the source of iron.

FIG 1—Beryllium-iron system developed by Gordon,⁶ based on preliminary studies leading up to the present investigation.

APPARATUS AND PROCEDURE

The alloys were prepared in a vacuum induction furnace, using beryllia crucibles. The resulting ingots were approximately 2 in. high \times 1½ in. diam, and weighed 60–150 g depending on composition. The ingots were analyzed top and bottom, and accepted only if the determinations checked within ± 0.1 wt pct.

Thermal analysis and solution-quenching experiments were performed in the vacuum furnace shown in Fig 2. It consisted of a molybdenum-wound alundum core, mounted in a water-jacketed steel shell with electrical and vacuum fittings introduced through the sides, thus leaving the top and bottom completely accessible for various interior designs.

The interior arrangement for the thermal analysis runs is shown in Fig 3. The thermocouple was located with respect to the melt by means of a re-entrant tube integral with the bottom of the beryllia crucible. The rate of temperature rise or fall was controlled by varying the furnace volt-

age through an induction regulator driven by a telechron motor. The rates were usually adjusted to 1–2°C per min. Temperatures were recorded automatically for the survey runs, and measured with a K-2 precision potentiometer for the critical determinations. Calibrated platinum-platinum rhodium thermocouples were used for all the critical determinations. It is believed that the accuracy of measurement was within $\pm 10^\circ\text{C}$ above 1350°C, and $\pm 5^\circ\text{C}$ below.

In the solution-quenching experiments, the temperatures were probably accurate to $\pm 2^\circ\text{C}$. Fig 4 illustrates how this operation was carried out in the vacuum furnace of Fig 2. Small pieces of the alloys to be treated were placed in thin-walled iron capsules for identification and guidance through the furnace. When the solution temperature was believed to approach or exceed the solidus, the iron capsules were lined with beryllia to avoid sticking or iron contamination. The beryllia linings were also employed when powder specimens were treated for X ray measurements. After the furnace

had been evacuated and stabilized at the predetermined temperature, the capsules were pushed into the furnace, one by one, via the charging tube shown at the top right of Fig 4. Each specimen was detained in the heating chamber for the desired time by a molybdenum vane operated from the outside, and then allowed to drop into an externally-cooled silicone oil bath. After all the capsules in the charging tube had been solution-treated and quenched, the bath was disassembled from below, and the samples recovered. Further details on the design and operation of the above equipment are being published elsewhere.

The metallographic techniques used were fairly standard, except for the alloys in the range of 8 to 45 at. pct iron (36 to 84 wt pct). The latter were extremely brittle, and were polished on a Graton semiautomatic unit.* No suitable etchant was found for these compositions. However, they could be examined successfully with polarized

* This polishing was done by Mr. Charles Fletcher at Harvard University.

FIG 2—Vacuum furnace used for thermal analysis and solution-quenching experiments. (See Fig 3 and 4.)

light. Alloys containing 0 to 8 at. pct iron were etched with 1 pct HF, while those containing 45–100 at. pct iron were etched with 1 pct nital.

The structures of the phases were studied by standard X ray diffraction procedures using Debye-Scherrer and Phragmen cameras with CoK_α radiation. Most of the solid solubility limits were determined by the lattice-parameter and disappearing-phase methods.

Experimental Results

The individual solid phases are first discussed, starting with beryllium and proceeding in the direction of iron. Following this, the thermal, X ray and metallographic data leading up to the diagram itself are presented in two sections: (1) 0–8 at. pct iron and (2) 8–100 at. pct iron. All compositions are henceforth expressed as atomic percent iron, until at the very end, the

FIG 3—Interior arrangement of vacuum furnace for thermal analysis. (See Fig 2.)

FIG 5—Inverse-rate thermal curves for vacuum melted beryllium stock.

proposed diagram is redrawn with iron at the left and compositions expressed as weight percent beryllium to comply with the convention adopted by the 1948 Metals Handbook. With this arrangement, the phase designations fall into proper sequence.

θ PHASE (Be)

Thermal analysis of the vacuum-melted beryllium stock revealed a double arrest near the melting point, both on cooling and heating (Fig 5). Other sources of beryllium, having different amounts of impurities, also displayed these two heat effects. The upper arrest varied from sample to sample, but the lower one remained quite constant, except when iron was present in excess of 0.1 at. pct. Furthermore, the ratio of the heat liberated (or absorbed) at the two arrests varied from sample to sample. Both Sloman⁷ and Losano⁸ have likewise observed a double break in the thermal curves for beryllium. Losano⁸ reported that the upper arrest is raised to 1284°C with

Table 2 . . . Summary of Phase Structures*

* Typical X ray diffraction patterns are shown in Fig 12 and 20.

increasing purity and the lower arrest completely disappears at extremely high purity (99.962 wt pct beryllium). Sloman⁷ also attributed the double arrest to impurities, oxygen in particular.

The same conclusion was reached in this work, but the possibility of an allotropic transformation occurring near the melting point was also considered. This alternative was finally judged to be improbable on the following grounds:

1. The heat involved in the lower arrest was too large relative to that of the upper arrest for these phenomena to be regarded as allotropic and melting transformations respectively.

2. Careful study of the temperature-time cooling curves (rather than the inverse-rate curves in Fig 5) indicated that the upper transformation actually took place over a temperature range, while the lower break constituted an isothermal hold. This suggested a binary liquidus and eutectic reaction, and not complete freezing followed by a solid-solid transformation.

3. In addition, when the resulting beryllium-iron diagram was drawn to include the hypothetical allotropic change, it called for completely solid phases in alloys of 0.5 and 1.5 at. pct iron at temperatures of 1190 to 1225°C (refer to Fig 10). However, when these alloys were quenched from this region, they displayed definite evidence of melting.

If the double arrest is caused by an impurity, other than iron, the beryllium-iron alloys under investigation should be considered as ternary rather than binary compositions. It was established that iron was not the active impurity because beryllium samples with as little 0.001 at. pct iron showed a marked double heat effect, very similar to that exhibited by the stock beryllium containing 0.016 at. pct iron. Moreover, all of the experimental findings on the beryllium-iron alloys were consistent with concept that (1) they belonged on a section through a ternary system, and (2) that the "pure" beryllium behaved as if the presence of an

impurity caused primary beryllium to crystallize over a range of temperatures down to a binary eutectic temperature where the rest of the beryllium and the impurity-constituent crystallized simultaneously and isothermally.

This is in line with the observations of Sloman⁷ who ascribed the eutectic to Be + BeO. However, in the present work, no eutectic configuration could be seen in the microstructure of the beryllium; nor could the BeO phase be identified as such, although there were many inclusions visible (Fig 6). Inasmuch as oxygen analyses were not available for correlation purposes, it appeared preferable to designate the impurity-constituent as *X*. These relationships will be discussed more fully in the section dealing with 0-8 at. pct iron.

The solid solubility of iron in beryllium⁸ was found to be quite limited (less than 0.4 at. pct iron) and no

change in lattice parameter could be detected. The lattice constants of beryllium are listed in Table 2, along with data for the other solid phases to be discussed.

§ PHASE (FeBe₁₁)

Misch⁵ found diffraction lines from a complex beryllium-rich phase judged to be FeBe₉. In the current investigation, a compound was located between 7.8 and 8.2 at. pct iron, which corresponds to the formula FeBe₁₁ (or possibly FeBe₁₂), rather than FeBe₉. All the diffraction lines from this phase can be indexed on the basis of a hexagonal cell of dimensions shown in Table 2. According to the measured density (2.50 g per cc), the number of atoms per unit cell is 18. This is a peculiar result because it implies that there are 1½ formula weights per unit cell. Until a complete solution of the structure by single-crystal analysis is available, the present findings cannot be rationalized.

The range of solubility in the ζ phase is too limited to show a variation of lattice parameter with composition. It transforms on heating via a congruent reaction at 1075°C into the ϵ phase. It is extremely difficult to polish because of brittleness, but when this is properly done, it can be easily identified in the microstructure under polar-

FIG 6—Inclusions in beryllium stock. Larger particles are beryllium carbide; smaller ones are probably a silicon-rich phase. Unetched. Mag. 500 X.

ized light by the feathery appearance illustrated in Fig 21.

ϵ PHASE (FeBe_5)

Misch⁵ determined the structure of this phase to be face-centered cubic and assigned the formula FeBe_5 . This was confirmed in the present work (Table 2) except that the phase was found to enjoy a wide range of homogeneity at elevated temperatures (7 to 18 at. pct iron). At lower temperatures,

however, the range becomes narrow (15–17 at. pct iron), but still includes the composition FeBe_5 (16.7 at. pct iron). The variation of lattice parameter with composition, obtained by solution quenching, is given in Fig 7.

Because of its cubic symmetry, ϵ does not exhibit extinction effects upon rotation under polarized light (Fig 21) and is thereby readily distinguished from ζ on the one hand and β on the other, both of which are optically anisotropic.

β PHASE (FeBe_2)

This compound was first observed by Oesterheld.² Later, Misch⁵ reported the structure to be hexagonal close-packed of the MgZn_2 type, and this was substantiated here (Table 2).

The β phase was found to extend from 21 to 37.5 at. pct iron, and Fig 8 shows the variation of the basal parameter with iron content. The c/a ratio does not change measurably over this range of composition.

β melts congruently at approximately 1480°C, corresponding to the composition 33 at. pct iron or FeBe_2 .

Metallographically, β is easily identified because of its polarizing effects. On the beryllium-rich side of the above range, the grains of β are uniformly clear (Fig 22), but at the iron-rich side, a fine lacy structure appears within the grains (Fig 23).

α PHASE (Fe)

Beryllium is appreciably soluble in ferrite, and its effect on the lattice parameter of body-centered cubic iron is given in Fig 9. The present results depart somewhat from those of Gaev and Sokolov,¹ and are in better agreement with the calculated parameter based on atomic radii.

The critical points of pure iron used in the final diagram were taken from the 1948 Metals Handbook as A_3 at

910°, A_4 at 1400° and $m.p.$ at 1539°C. No studies were made of the austenitic and ferritic phase boundaries. The gamma loop and alpha solubility limits of Gaev and Sokolov¹ were adopted.

0–3 AT. PCT IRON (0–35 WT. PCT)

The results of thermal analyses on cooling of alloys lying in this range are summarized in Fig 10. The liquidus line descends from “pure” beryllium, and reaches a minimum at 4.7 at. pct iron. This occurs at 1210°C, and corresponds to the maximum heat effect in the series. The lower arrest of beryllium descends with increasing iron, and meets the 1190°C isothermal line at about 3.0 at. pct iron, where it yields

the maximum heat effect in this series.

The phase fields outlined in Fig 10 were drawn to be consistent, not only with the thermal points shown, but also with the X ray (Fig 11) and metallographic results of the solution-quenching experiments.*

The latter observations were given more weight in cases where supercooling was suspected to have influenced the thermal arrests. For example, the two points at 950°C in Fig 10 were found to be in error because of supercooling. Hence, the isothermal reaction indicated at 1010°C was ascertained on the basis of the quenching experiments.

* Due regard was also given to the phase rule as applied to ternary systems.

Fig 12 offers a comparison of the diffraction patterns of several alloys after quenching from above and below 1010°C.

The transformations corresponding to the various lines in Fig 10 and 11 are deducible from the microstructures. Up to 2.9 at. pct iron, the as-solidified alloys exhibit increasing amounts of an eutectic-like structure, (Fig 13 and 14) which is evidently connected with the 1190° isothermal line. At the same time, the amount of primary θ diminishes. Beyond 3.0 at. pct, a coarse duplex structure appears and reaches a maximum at 4.7 at. pct iron, corresponding to the 1210° intersection. A comparison of the two “eutectics” is found in Fig 15.

| TREATMENT | ANGLE θ FOR Co K α RADIATION | | | ATOMIC % Fe | PHASES | WEIGHT % Fe |
|------------------|--|----|----|----------------|--------------------|----------------|
| | 0 | 45 | 90 | | | |
| ALL BELOW 1000°C | | | | 8.0 | ζ | 35.4 |
| | | | | 13.6 | $\zeta + \epsilon$ | 49.2 |
| | | | | 15.3 | $\zeta + \epsilon$ | 52.8 |
| | | | | 20.5 | $\beta + \epsilon$ | 61.5 |
| | | | | 25.5 | β | 67.9 |
| | | | | 32.0 | β | 74.2 |
| | | | | 44.7 | $\alpha + \beta$ | 83.5 |
| | | | | 100. | α | 100. |

FIG 20—X ray diffraction patterns of alloys containing 8–100 pct iron. Annealed below 1000°C.

When the iron is increased above 4.7 at. pct, primary grains of ϵ begin to appear in conjunction with the two “eutectics” (Fig 16). The mottling in the primary ϵ is due to partial decomposition into $\theta + \zeta$ via the eutectoid reaction at 1010°C. In some instances, even the ϵ associated with the “eutectic” structures undergoes such decomposition (Fig 17). However, if the alloys are quenched from above 1010°C, the phase is retained intact. As shown in Fig 13 and 17, some precipitation from the θ phase occurs during slow cooling, in accordance with the sloping solubility limit.

It is believed that the coarser of the two “eutectics” results from the univariant reaction $L \rightarrow \theta + \epsilon$ in the vicinity of 1210°C, and the finer one from the nonvariant reaction $L \rightarrow \theta + \epsilon + X$ at 1190°C (Fig 10). Unfortunately, no evidence was obtained as to the identity of the X constituent. Fig 17 shows primary grains of θ separated by a network of the ternary eutectic. The θ particles and ϵ matrix of the eutectic are clearly distinguishable, but there is also a third phase (polished in relief) in the form of needles that run through the eutectic, causing jagged interfaces between the θ and ϵ . No diffraction lines attrib-

utable to this phase were observed.

8–100 AT. PCT IRON (35–100 WT. PCT)

Since the assumed impurity was introduced in proportion to the beryllium content, it was reasonable to expect the ternary behavior of the system to vanish gradually with increasing percentages of iron. Thus, the higher iron range could be treated as a regular binary diagram without undue violation of the phase rule.

The results of thermal analysis for the above composition range are plotted in Fig 18. The liquidus rises to approximately 1480°C at the melting point of the compound FeBe_2 (β), then falls to 1165°C (the eutectic of β and α), and finally rises to 1539° at the melting point of pure iron.

The solution-quenching experiments are summarized in Fig 19. Fig 20 illustrates the diffraction patterns of typical alloys in this range.

From the shape of the liquidus lines and extension of the solid phase boundaries, a peritectic reaction was deduced at approximately 1375°C: $L + \beta \rightleftharpoons \epsilon$. No thermal evidence for this reaction was found but the microstructure of an alloy in this range did show signs of β surrounded by ϵ . Furthermore, the

peritectic temperature agrees with that of Gordon's diagram in Fig 1.

The micrographs in Fig 21 to 25 illustrate the types of structures observed. Fig 21 shows a mixture of ζ (light and feathery) and ϵ (dark masses). Fig 22 and 23 are examples of β . Fig 24 typifies the primary β plus eutectic ($\alpha + \beta$) structure, and Fig 25 shows an iron-rich alloy with β precipitated from the α solution matrix.

Final Diagram

The entire diagram is assembled in Fig 26. At the beryllium-end, the ternary behavior is eliminated by collapsing the three-phase regions in an attempt to estimate the nature of the true beryllium-iron binary system. This practice is somewhat arbitrary because there is no information as to the critical temperatures and compositions in the absence of the interfering impurity. However, it is likely that the observed liquidus and solidus temperatures would rise slightly with increasing purity, as found by Losano⁸ for beryllium itself.

Fig 26 embodies all these considerations, and is redrawn to conform to the method of presentation adopted by the 1948 Metals Handbook.

Conclusions

1. The available beryllium (99.4 wt pct) was sufficiently impure to exhibit a double arrest at the melting point.

2. Because of the binary nature of this beryllium, the beryllium-iron diagram investigated turned out to be a section through a ternary system. The experimental data were analyzed on this basis, and then the beryllium-iron binary was deduced by allowing the three-component relationships to degenerate into a two-component diagram, thus eliminating one degree of freedom. This approximation was only necessary at the beryllium-end of the system.

3. The solid phases in the system have been identified as listed in Table 2.

4. The beryllium-iron diagram contains two eutectics: one at 1225°C, $L_{7.5} \rightleftharpoons \theta_{0.4} + \epsilon_7$; and the other at 1165°C, $L_{64} \rightleftharpoons \beta_{37} + \alpha_{67}$. There is also a peritectic at 1375°C, $L_{16} + \beta_{21} \rightleftharpoons \epsilon_{18}$; and an eutectoid at 1010°C, $\epsilon_7 \rightleftharpoons \theta_{0.1} + \zeta_8$. The subscripts indicate atomic percent

iron. The corresponding weight percentages are given in Fig 26.

5. The ζ phase decomposes congruently on heating into ϵ at 1075°C, and the β melts congruently at about 1480°C.

6. There are appreciable ranges of solubility in the α , β and ϵ phases, but very limited solubility in the ζ and θ phases.

Acknowledgment

The authors wish to express their appreciation to Mr. Paul Gordon for permission to publish Fig 1 which summarizes his preliminary work leading up to the present investigation; to Dr. A. R. Kaufmann for his criticisms and aid; to Mr. A. B. Bompane who assisted in the thermal analyses; to Miss H. P. Roth for the general metallographic work; to Mr. Charles Fletcher for the special polishing of the brittle alloys; and to Mr. V. M. Mahady for making the beryllia crucibles.

The research was carried out in the Department of Metallurgy at Massachusetts Institute of Technology under the auspices of the Manhattan Project, Contract No. W7405-eng-175.

The Cobalt-chromium Binary System

By A. R. ELSEA, A. B. WESTERMAN, Junior Members, and G. K. MANNING, Member AIME

DISCUSSION

(G. E. Doan and W. L. Fink presiding)

A. H. SULLY*—There are two points relating to this paper which I would like to discuss.

The first relates to the purity of the alloys. I note that, whereas all the alloys examined were analyzed for nitrogen, no estimations of the oxygen content appear to have been made and, in discussing the purity of the materials, although the authors refer to the oxygen content of the electrolytic cobalt (0.034 pct), they appear to have ignored the oxygen present in the electrolytic chromium. It was first shown by Adcock⁸ that the oxygen content of electrolytic chromium may be, and usually is, considerable, the content of chromium oxide Cr_2O_3 being commonly of the order of 1–2 pct. Brenner, Burkhead and Jennings⁹ have recently confirmed this fact and have made a comprehensive investigation of the variation of the oxygen content with conditions of electro-deposition. Work in progress at the Fulmer Research Institute on the preparation of high purity chromium-rich alloys has illustrated the difficulty of removing the oxygen content; and we have found that chromium-rich alloys can continue to oxidize when melted under moderate vacuum conditions (5–20 microns). For this reason, chromium-cobalt alloys with up to 20 pct cobalt, made from electrolytic chromium containing initially about 1.6 pct Cr_2O_3 may contain, after vacuum melting, up to 2.5 pct Cr_2O_3 . The oxygen content may be determined readily by dissolving the alloy in dilute acid and weighing the insoluble residue of Cr_2O_3 . The same method may be used for the determination of the oxygen content of electrolytic chromium, if the chromium is first heated for a period of a few hours at a temperature of about 800°C.

While the oxide content is unlikely to have any serious effect on the phase transformations, it must be remembered that the chromium content of the oxide will be withheld from solid solution and this will have a minor effect on the location of the boundaries in the chromium-rich alloys. A statement by the authors of the oxygen content of their alloys would enable an assessment to be made of the probable precision in the location of the $\epsilon/\gamma + \epsilon$ phase boundary.

The second point which I wish to make concerns the identity of the γ phase. During a preliminary survey of the cobalt-chromium system, my colleague, Mr. T. J. Heal, and I¹⁰ found that this phase was isomorphous with the sigma phase, of the iron-chromium. Andrews,¹¹ in commenting on our result, has since stated that there appears to be a third isomorphous phase in the system Fe-V. The present investigation places the composition of this phase at the CO_2Cr_3 composition, confirming the earlier work of Wever and Haschimoto.¹² In the iron-chromium system the isomorphous sigma phase forms at the ratio Fe-Cr. In both systems, however, solution seems to be confined to the low chromium side of the relevant stoichiometric composition. The reason for the variation of the stoichiometric ratio for the isomorphous phase between the Co-Cr and the Fe-Cr system is an interesting subject for speculation, and further study of this phase in the two systems may throw further light on the difficult subject of atomic bonding in alloys of the transition metals.

N. J. GRANT* and L. W. KATES*—Several points in this paper that are not quite clear or in complete agreement with our work at Massachusetts Institute of Technology include the following:

The structure of an all-alpha specimen (Fig 4) could be interpreted as a two-phase structure rather than a single phase one. Specimens of chromium contents 10.6, 16.8, 23.0, and 28.8 pct when heated at temperatures of from 1800 to 2200°F (980 to 1205°C) for periods of time ranging from 1 to 48 hr followed by water quenching, invariably showed both F. C. C. and H. C. P. lines on X ray diffraction examination. In addition, these same specimens, when examined metallographically, using such etchants as chrome regia and Marble's Reagent, showed a rather poorly defined but unmistakable two-phase structure. We wondered, in those treatments where the initial structure was "all alpha," if this were checked by X ray diffraction patterns. It was not made clear, but we presumed that the alpha structure was retained at room temperature by water quenching. Our work has indicated that there is a metastable martensitic form of beta which is formed on quenching from within the alpha range which accounts for the H. C. P. lines and the microstructure observed in quenched alpha specimens. If that is the case, the so-called

"all alpha" structures are not truly equilibrium structures. It would seem that a true equilibrium alpha structure does not exist at room temperature and that a study of the α to β transformation would best be done by transferring the hot all alpha specimen directly to the aging temperature without the intermediate quenching step.

Although no attempt was made at Massachusetts Institute of Technology to establish the boundaries of the gamma phase field, the presence of gamma phase in alloys as low in chromium as 15 pct seems questionable. It is interesting to note that alloys V-20, V-26, and V-31 were cold worked initially to form beta and all these showed a gamma precipitate when aged for 65 hr at from 600 to 850°C. Alloy V-14, however, which had a homogenized structure initially, did not. It seems possible, therefore, that the so-called gamma precipitate is, in fact, some residue of the initial cold-worked structure. This is further suggested by the fact that Alloy V-36 which also had a homogenized initial structure showed no gamma precipitate at 600°C, although at 650°C and above, presumably, massive gamma, as exemplified in Fig 8, was found.

We took note of the treatments for developing gamma shown in Table 4 and repeated one of the experiments using our 28.8 pct chromium alloy. The specimen was heated at 1000°C for 1 hr and water quenched and metallographic examination showed the usual two-phase structure. The specimen was then held for 50 hr at temperatures of 875, 850, 830, and 890°C with metallographic and X ray examination being made between each different treatment. The structure in every case was the same, namely a single phase H. C. P. structure. There was no evidence of gamma precipitate similar to Fig 7 resulting from any of the treatments. Several attempts were made to use the etchant described in the paper for identifying the gamma phase; all were unsuccessful. The etchant finally adopted was Marble's Reagent which showed the beta grain boundaries quite well.

Regarding etchants 1, 2, and 3, used by the authors, we never, at any time, were successful in using them as described in the paper on our own alloys. We are not surprised that prior alpha structure did not transform to beta in 50 hr in alloys of less than 20 pct chromium. We did note, however, that a 28.8 pct chromium alloy transformed from alpha to beta com-

*Fulmer Research Institute, Stoke Poges, Buckinghamshire, England.

⁸ References are at the end of discussion.

*Massachusetts Institute of Technology.

FIG 17—Plots of patterns of various alloy compositions of cobalt and chromium.

paratively easily when cooling in a dilatometer at a rate of about 5°C per min. We found that the 23 and 28.8 pct chromium alloys transformed readily from alpha to beta and vice versa, simply by heating and cooling in a well insulated furnace, but that the 10.6 and 16.8 pct alloys did not transform on cooling (alpha to beta) even at very slow cooling rates.

H. S. AVERY*—Rockwell hardnesses are mentioned in the paper, but I did not see any values. I should like to suggest that the authors will make this more valuable as a reference if in their written reply to the discussions they would include microhardness readings for the various constituents, and also give enough of their X ray crystallographic data to enable other workers to check their data against

those described in this paper.

W. O. SWEENEY*—The authors should be complimented on their very thorough investigation. We feel it is very timely now because of the necessity to know more about the high temperature alloys, as well as to obtain fundamental data which will enable the development of newer and better alloys for even higher temperatures.

The results of the work which were reported are in substantial agreement with the previous work that has been published and the work done at Union Carbide and Carbon Research Laboratories in Niagara Falls. It is also in line with the work we have done at the Haynes Stellite Co. Of course, the latter has been devoted primarily to more complex alloys.

However, we think it is noteworthy

* Haynes Stellite Co.

that the results the authors have obtained are not inconsistent with what we found in more complex alloys of this type.

A. R. ELSEA (authors' reply)—Mr. Sully has raised a very interesting question regarding the oxygen content of the cobalt-chromium alloys studied in this investigation. The electrolytic chromium used as melting stock in preparing these alloys contained 0.28 to 0.50 pct oxygen. Alloys V-7, V-20, V-26, and V-31, listed in Table 1 of the paper, contained 0.015, 0.14, 0.09, and 0.18 pct Cr₂O₃, respectively, as determined by a wet analysis method similar to the one described by Mr. Sully, but in which a correction was made for the amount of chromium nitride present in the residue. Microstructures of the vacuum-melted alloys, such as those described above, contained numerous oxide inclusions, while the

structures of the alloys melted in an alundum crucible under purified argon were almost free from oxide inclusions. After considerable study, it was concluded that chromium oxide in the melt went into solution in the alundum crucible, thus lowering the oxygen content of the melt.

The observation made by Mr. Sully that the cobalt-chromium gamma phase is isomorphous with the sigma phase of the iron-chromium system substantiates similar observations made at Battelle.

Dr. Grant and Mr. Kates have raised a number of questions regarding phase identification, experimental techniques, and interpretation of the data. In our opinion, the specimen shown in Fig 4 of the paper was alpha phase at the heat-treating temperature used; but upon cooling to room temperature partial transformation to beta phase occurred by a martensite type reaction similar to the reaction observed in pure cobalt by Troiano. This explains the acicular structure observed in Fig 4 and also partially accounts for the diffuse pattern of beta phase observed in the X ray diffraction patterns shown in Fig 17 of this discussion. It was because of this partial transformation during the quench that the aged specimens with alpha prior structures were transferred directly from the preheating furnace to the aging furnace, as described in the paper.

There is no question in our minds regarding the presence of gamma phase in cobalt-chromium alloys containing as little as 20 pct chromium. All of the binary alloys containing 20 pct or more chromium when aged at temperatures 20 to 50°C below the lower limit of the alpha-beta transformation range were found to contain gamma phase. The presence of gamma phase in these specimens was established by both metallographic and by X ray diffraction studies.

Dr. Grant's unsuccessful attempts to use the metallographic etchants described in the paper are difficult to explain. We have used these etchants throughout the study of the binary system and in our studies of the cobalt-chromium-iron, cobalt-chromium-nickel, and cobalt-chromium-nitrogen systems with success. The higher chromium alloys require a much longer etching time, but if the proper etching technique is used, metallographic

identification of the phases in this system is not difficult.

The Rockwell hardness impressions referred to by Mr. Avery were made on metallographic specimens to determine the nature of the slip lines or the type of fracture that was produced in the various phases by slight cold work. The microhardness values requested by Mr. Avery are as follows:

| Phase | Knoop Hardness (500-g load) |
|-------------------------|--------------------------------|
| Gamma..... | 940 to 960 |
| Epsilon (84 pct Cr).... | 630 to 686 |
| Beta (31 pct Cr)..... | 330 to 360 |
| Alpha* (31 pct Cr).... | 250 to 340 |

* The hardness of alpha was determined at room temperature and, therefore, it was not pure alpha but was alpha plus beta which formed while cooling to room temperature.

The following discussion of the X ray diffraction data was prepared by Dr. C. M. Schwartz of the Battelle staff, who conducted the X ray diffraction studies:

Plots of representative X ray patterns of alloys of various compositions and heat treatments are shown in Fig 17. Filings were used in Debye cameras with Co, Ni, or CrK radiation; or where greater resolving power was required, block samples were used with CrK radiation in a 20-cm-diam unsymmetrical focussing camera. Since the techniques varied, the photograms could not be compared directly, and it was necessary to resort to the graphical plot in Fig 17.

Pattern A, obtained from a 20 pct chromium sample quenched from 900°C, not far above the transformation zone, illustrates the existence of the "diffuse" hexagonal beta phase in samples quenched from the high-temperature F.C.C. alpha region. The corresponding indices of the reflections are indicated above the pattern. The appearance of beta is in agreement with that reported in pure cobalt by Edwards and Lipson.[†] Some lines are sharp, others diffuse, owing to stacking faults as explained by these authors. The existence of this faulted hexagonal phase is well correlated with the Widmanstätten-like appearance of the microstructure of alpha phase in Fig 4 of the paper. The question whether this structure results in part from quenching strains has not yet been settled from X ray data. Small amounts of "diffuse" hexagonal remain in samples of filings examined in a high-temperature camera

[†] *Proc. Roy. Soc.*, (1942) 180A, 268.

at temperatures just above the transformation zone, after moderate holding times. The amount does not increase on rapid cooling to room temperature; however, the strain introduced in this way is not comparable to that in a quenched block sample. Experiments are contemplated in which samples will be held and examined at temperatures far above the transition to see whether the hexagonal structure will tend to disappear.

It is to be noted that the (111) cubic and (0002) hexagonal reflections are resolved; complete resolution is attained in the focussing camera, using chromium radiation. This makes it possible to compare the relative intensities of the lines of the hexagonal phase. In spite of the diffuse nature of some of the lines, there is no marked discrepancy among the intensities, as has sometimes been claimed for cobalt itself.

Patterns B and C were obtained from 20 pct and 31 pct Cr block samples hot forged in the beta region, and subsequently heat treated and quenched from 700 and 800°C, respectively. Under these conditions sharp hexagonal beta-phase patterns are obtained free from alpha. The two strongest lines of gamma phase also appear faintly, in agreement with the phase diagram in Fig 3. Note again that the relative intensities of the first three lines of beta agree in Patterns A, B, and C.

Patterns D, E, and F contain gamma phase. Pattern E is single-phase gamma, with lattice spacings corresponding almost to the limit of chromium solubility. The solubility range is small, and the shift in spacing is readily detected only in the back-reflection lines. Pattern G, that of the chromium-rich solid-solution phase epsilon, is given so that its presence in Pattern F may be easily identified.

Mechanism of Precipitation in a Permanent Magnet Alloy

By A. H. GEISLER, Junior Member AIME, and J. B. NEWKIRK

DISCUSSION

(G. E. Doan and W. L. Fink presiding)
W. L. FINK*—For some years many

* Aluminum Co. of America.

of us have believed that the age hardening mechanism consisted simply of precipitation by nucleation and growth in which the precipitation occurred by the usual Widmanstätten mechanism, and

during the early stages of which the precipitate is coherent with the matrix.

Dr. Geisler has been working on this problem—one system after another—and he has succeeded in proving that mechanism for several alloys. He is doing a very excellent job. I feel that today

he skipped rather lightly over one of the important parts of this work—the streaks that are obtained on the Laue patterns from single crystals. I wonder if he would like to say a little more about the streaks.

A. H. GEISLER (authors' reply)—The interpretation of streaks in Laue photographs represents a specialized but important part of the precipitation problem. It has been demonstrated elsewhere⁸ that the streaks can be interpreted generally as the result of small dimensions of the precipitate particles that have a new structure related to the matrix by coherency. As such, the small particles should warrant no special consideration as a step in the precipitation process discrete from the larger, coherent particles that produce normal sharp diffraction. This was suggested by the discussor 8 or 10 years ago and has since been confirmed for several alloys. Indeed, the present study illustrates that age-hardening need not be contingent upon the structure that is responsible for streaks since the major part of the hardening of Cunico occurs after the particles have grown to a size large enough to produce sharp diffraction.

R. M. BRICK*—This aging is a little different from the normal precipitation process. Constitutionally it is almost a eutectoid reaction. You use the word "recrystallization" in discussing the lamellar stage of precipitation. I assume that you imply that if reheated after complete softening, when again in the single phase structure, there would be a completely different matrix grain structure than there was originally. Is that true?

A. H. GEISLER—The difference between the precipitation process in this

type alloy and the usual is that here the precipitate has the same structure as the matrix whereas usually the precipitate has a structure different from the matrix. In this respect the reaction here is more remote from the eutectoid reaction where both decomposition products usually have structures different from each other and different from the parent phase. Furthermore, the basic constitutional difference exists: that of the absence of a specific reaction temperature and composition as in the eutectoid reaction. Grain refinement in some alloys can be induced by the nodular reaction. The best evidence for this has been obtained on single crystals using the Laue X ray diffraction technique. Single crystals of some alloys, notably Cu-Be, Ag-Cu and Ni-Au are replaced by a polycrystalline aggregate when heat-treated crystals are aged and re-solution heat treated.

A. E. FLANIGAN*—I should like to comment on Dr. Geisler's remarks concerning a novel method for obtaining grain refinement.

It is implied that in the case of certain precipitation-hardening alloys it has been found possible to obtain grain refinement of the solid solution by means of a process involving precipitation followed by resolution. Presumably, precipitation of the discontinuous "lamellar" type in the region of the grain boundaries of the solid solution is attended by recrystallization of the matrix. Upon re-solution, it is implied, the new orientations of the previously lamellar patches are preserved thus effecting grain refinement of the solid solution.

This mechanism and its possible practical importance interested me several years ago and at that time an attempt

* University of California.

was made to induce grain refinement in this manner. A magnesium base casting alloy containing 9 pct aluminum and 2 pct zinc was employed. (ASTM B80-45T grade AZ92.) About ten cycles of the above-described treatment were employed and measurements of the grain size of the solid solution were made after each cycle. No changes in grain size were detected, however, even after this large number of cycles.

A. H. GEISLER—The application of the nodular reaction as a grain refinement method depends both upon alloy and thermal treatment. Since this is a recrystallization of the matrix it can be suppressed by the relief of strain through prior recovery in much the same manner as the suppression of recrystallization of cold worked metal. Thus, by slow heating to the solution temperature, it has been possible to recover single crystals by reabsorbing the recrystallized nodules. For grain refinement, such a reversion would have to be prevented; the nodular reaction would have to be carried to a sufficient degree of conclusion by aging and the heating rate to the solution temperature would have to be sufficiently fast to avoid reversion to the original grain structure. Naturally, if the rate of grain growth to a stable structure is very rapid at the solution heat treating temperature, as it may well be in some alloys, this method would be of little avail as a possible method of grain refinement.

Some Effects of Applied Stresses on Precipitation Phenomena

By WALTER L. FINLAY and WALTER R. HIBBARD, JR., Members AIME

DISCUSSION

(G. E. Doan and W. L. Fink, presiding)

V. G. PARANJPE*—Have the authors investigated, or theoretically looked into, the effect of these large hydrostatic pressures on the equilibrium diagram itself? Of course, the change in the equilibrium relationships would depend on the amount of heat evolved, and the change of volume associated with the reaction. The effect may be computed by straightforward thermodynamics. It may be that the effect of hydrostatic pressures

which the authors describe in their paper might arise appreciably from the change in the equilibrium relationships only.

W. L. FINLAY (authors' reply)—Mr. Paranjpe has raised a very interesting point. We have no information on the effect of pressure on this system and have had no opportunity to investigate it.

I might point out that intermittently through the aging sequence specimens were removed for periods up to two hours in order to make the hardness measurements. Occasionally specimens were examined microscopically and nothing unusual compared to atmosphere-pressure-aged specimens was noticeable

under the microscope.

Also, the hydrostatic-aged specimens had hardness properties, which, although they were significantly different from atmosphere-pressure-aged specimens, nevertheless were not of a different order such as no hardening at all. This would make me wonder if the solubility relationship had been markedly changed, but I have no information on that.

C. S. BARRETT*—If you had examined the microstructures, would you say whether there is a tendency for orientation of the precipitates as a result

* Massachusetts Institute of Technology.

* University of Chicago.

of the applied stresses?

W. L. FINLAY—I am afraid that again we have no data to offer on that point. Optical microscopy gave no pertinent evidence and no X ray work was done in the investigation.

C. S. BARRETT—Did you happen to notice whether the precipitate tended to be aligned on slip planes, or was it distributed generally, and with equal numbers of precipitated particles on the different crystallographic planes that are equivalent in the matrix?

W. L. FINLAY—At the aging temperature involved (100°C), Widmanstatten figures are not developed in these alloys and precipitation particles were aligned on slip planes.

R. M. BRICK*—Do you have any data regarding the volume changes involved in the systems?

W. L. FINLAY—In so far as 100°C aging is concerned, there is a volume contraction in Al-Zn and Al-Cu; data are not available for 75S.

R. M. BRICK—If there is volume contraction, then you would expect pressure to accelerate precipitation just from a volume standpoint?

W. L. FINLAY—Yes, you would expect more precipitate to come out from that standpoint. You are placing the matrix under compression, and, in the Al-Zn case, the zinc is in tension and you are relieving the elastic strain. Therefore, you would tend to extend the amount of coherency. Both Drs. Barrett and Brick have touched on the interesting possibility that the application of external stresses during aging might affect the mode of precipitation, that is, by changing the relative amounts of precipitation on different matrix planes which, although crystallographically equivalent, are differently oriented to an applied uniaxial tensile stress; or by changing the plane of precipitation by altering the relative spacings of matrix and precipitate. An investigation of these possibilities using single crystals would appear to be worthwhile.

G. CHAUDRON,† J. HERENGUEL‡ and P. LACOMBE§ (*Translation*)—The paper by Messrs. Finlay and Hibbard draws attention to the importance of stresses on the kinetics of structural hardening, particularly at a temperature of 100°C where abundant precipitation of a second phase can be observed in most solid solutions of aluminum.

We should like to call attention to some observations which we made with regard to these alloys. We have shown¹² that structural hardening is very rapid at room temperature for an alloy containing 12 pct zinc. Moreover, in the

FIG 17—Intergranular decohesion observed spontaneously on aluminum alloy containing 12 pct zinc, electrolytically polished then aged at 20°C after quenching from 400°C. $\times 300$.

FIG 18—Aluminum-zinc-magnesium alloy hardened at room temperature and then stressed after electrolytic polishing. $\times 150$.

course of a more or less prolonged aging this group of alloys starting with a zinc content greater than 3 pct presents, depending on composition, a very important phenomenon which we have called "intercrystalline decohesion."¹³ This phenomenon is characterized by intergranular separation, producing a very great brittleness of the alloy (Fig 17).

This brittleness can be observed both in hardening under vacuum and in the presence of more or less humid air. In addition, an external mechanical stress applied to the metal accelerates this cohesion¹⁴ whether the tested specimens are exposed to air or are protected by plating, varnish or anodic oxidation. The resulting fracture is definitely inter-

FIG 20—Macrograph of Intercrystalline Fracture of 12 pct Al-Zn after 5 hr at 100°C under 20,500 psi Tensile Stress. Tensile specimen was $\frac{1}{2}$ in. diam. Original magnification 13 \times . Reduced approximately one-half in reproduction.

granular (Fig 18) as found by Finlay and Hibbard at a temperature of 100°C.

As regards the hardness tests made by the authors, we are happy to notice complete agreement with our own tests carried out in 1943 on the same alloys, prepared likewise by starting with pure metals. (Fig 19). With regard to an alloy richer in zinc, 20 pct for example, it becomes impossible to perceive an increase in hardness after quenching, the latter taking place in a few seconds. In the course of the same study, we determined the specific effect of certain impurities, particularly iron and magnesium, on the kinetics of hardening. Additions of iron restrain the intensity

of hardening without slowing it up. Magnesium, on the contrary, even in extremely small quantities (0.02 pct) reduces the hardening speed. Thus one realizes that preceding studies made on impure alloys were not able to reveal this structural hardening.

Finally, it seems that after tests made on Al alloys containing 12 pct Zn, Messrs. Finlay and Hibbard intended to associate the phenomenon of retrogression with the particular way of aging under stress. Although the authors confirmed that 200°C was the optimum retrogression temperature for Al-Cu alloys, they adopted for their creep aging tests on this alloy the temperature of 100°C. It

seems to us that the choice of this temperature no longer allows comparison of these two alloys from the point of view of the mechanism of redissolving the mass of atoms in the course of retrogression.

W. L. FINLAY (authors' reply)—The interesting discussion contributed by Messrs. Chaudron, Herenguel, and Lacombe is very welcome. The authors were familiar with the publications of these investigators and, in common with a great many others, accord them the greatest respect. The following remarks are offered regarding the various points raised by these discussers:

1. The spontaneous "intercrystalline

decohesion" discussed by Messrs. Chaudron, Herenguel, and Lacombe was never observed by us in an experience comprising perhaps a dozen ingots with compositions from 8 to 25 pct zinc from which several hundred specimens were heat treated and observed on occasion over a two-year period. The discussers' micrographs establish very clearly, however, that their specimens did suffer intergranular fracture, and we have no explanation for the apparent discrepancy. The brittle, intercrystalline fracture we reported is illustrated in the accompanying macrophotograph (Fig 20). Unlike

the spontaneous failures reported by the discussers, all of ours occurred after a period of stress at an elevated temperature.

2. The very rapid age hardening at room temperature of quenched high purity aluminum-zinc alloys, shown in our paper and in the discussers' Fig 19, was first reported by Fink and Van Horn* based on both hardness and electrical resistance. Since this feature was only of incidental interest to our main

purpose, space did not permit mentioning the gratifying agreement with the work of the French investigators.

Diffusion of Carbon in Austenite with a Discontinuity in Composition

By L. S. DARKEN, Member AIME

DISCUSSION

(R. Smoluchowski and M. L. Fuller, presiding)

R. SMOLUCHOWSKI*—Thank you for the very interesting paper. It seems to me that these experiments provide a classical example of the role of activity in diffusion. You mentioned that in your experiment you had a rather wide two-phase region. This is possible in a ternary system only if there is migration of the third component and I do not think that under the conditions of your experiment this was possible.

L. S. DARKEN (author's reply)—The two phase region in the first experiment (Fig 1) does indeed arise by virtue of the migration of the third component (carbon). In a binary system there can be no gradient of activity in a two phase region and hence such a region cannot be obtained by isothermal diffusion. In a ternary system, however, a two phase region is not incompatible with an activity gradient. In fact the data of R. P. Smith demonstrate that in the two phase region (austenite + ferrite), at constant ratio of iron to silicon the activity of carbon rises, though slightly, with increasing carbon content.

V. G. PARANJPE†—I would like to ask Dr. Darken if this technique would not be a godsend in estimating the influence of alloying elements on the activity of carbon. For example, the steel contain-

ing various alloying elements might be welded on to an alloy in which the activity of carbon is known. The diffusion experiment would thus give an approximate idea about the change in the activity of carbon due to the presence of alloying elements in the former steel.

L. S. DARKEN—Mr. Paranjpe's suggestion seems good in principle. As to whether this method would be easier than others would depend upon the particular circumstances. This diffusion method is inherently longer than the gas equilibration method used by Smith and requires a multiplicity of analyses for each sample. However, the diffusion method does not require such precise control of the gas atmosphere and might be adaptable to a relatively uncontrolled atmosphere—for example, by plating the "sandwich" with an element relatively impermeable to carbon.

J. T. MILEK*—I wonder if the diffusion could also be explained as an ionic mechanism—that is, a movement of the carbon ions, if we could say they exist. I do not know if there is such a thing as a carbon ion in steel.

It was brought out recently that carbon can migrate under the influence of an electric current—a dc current electrolysis. I wonder if you would see this reaction by performing an electrolysis test, instead of waiting 14 days, that is, to impress a high d-c current through the weld and also note that diffusion or transportation of carbon, whether it is ionic or atomic.

L. S. DARKEN—I agree with Mr. Milek's implication that the carbon in

austenite is ionic in nature. It migrates under the influence of a potential gradient (direct current); I have observed this effect myself. However, I do not believe anything can be gained in the present type of experiment by the passage of an electric current. In fact, I would expect that the potential gradient would give rise to approximately equal force on the carbon atoms no matter which side of the weld, and that the resulting motion of the carbon would tend to mask the effect considered in this paper. The superimposed effect of the electric current would certainly complicate the interpretation at any rate.

Since the publication of this paper, I have been informed of the prior work of Seith and Bartschat¹² on this subject. They welded an iron-carbon alloy (0.965 pct C) to each of several low carbon alloys (Ni-Fe, Co-Fe, Cr-Fe, Cu-Fe) and held each welded specimen at 940°C for one day. Although "uphill" diffusion was not encountered under these circumstances, a discontinuity in carbon content at the weld was found in several cases. This discontinuity was most pronounced at the weld involving a 19.2 pct nickel alloy—the carbon being 0.39 pct on the high nickel side and 0.66 pct on the iron-carbon side of the weld. A slight discontinuity (about 0.07 pct C) was found at the weld involving a 10 pct cobalt alloy. No discontinuity was found with the copper (2.7 pct Cu) or chromium (10.2 pct Cr) alloy.

An Electron Diffraction Study of Oxide Films Formed on Nickel-chromium Alloys

By J. W. HICKMAN, Member AIME, and E. A. GULBRANSEN

DISCUSSION

(R. Smoluchowski and M. L. Fuller, presiding)

F. R. MORRAL*—This paper presents some very interesting data on two types of Ni-Cr alloys. The authors give, it is believed, too much importance to the oxide films formed as being the controllers of the useful life of the alloys at high temperatures. The data, summarized here-with in Table 6 by types of life (more than 100 hr, 50 hr) seem to indicate that alloying elements, such as Si and Mn, are of special significance. The effect of the small amounts of Zr, Ca and Al cannot be properly evaluated. The study of another set of alloys with these elements present and 1.7 pct Mn would be necessary.

The presence of the 1.7 pct Mn is definitely detrimental to the useful life, although the oxide film is the same as that on the alloy showing the longest life (245 hr). Heating and cooling cycles may have an effect on the oxide films, although Fig 7 and 8 show that the high temperature oxides are retained on cooling down to room temperature for all six alloys.

The somewhat larger amount of Cr (3.5 pct) is beneficial even at higher temperatures. This effect was not so pronounced on the alloy containing 1.3 pct Si.

It may be of interest to mention that a salt bath has been found which at 1850°F (1010°C) in less than 10 min. removed the difficulty of eliminating film present on nichrome rods and wire.

The authors are to be thanked for making available this type of valuable data.

E. A. GULBRANSEN (authors' reply) We are indebted to Dr. Morral for his interesting comments. The original choice of heater alloys was made on a historical basis. It would be of scientific interest now to study the effect of one alloying element at a time on both the lifetime and structural factors of the oxide film. This would require a long and intensive study.

We have not made in our conclusions comparisons between alloys of the 80 Ni-20 Cr and the 61 Ni-16 Cr-23 Fe series because the useful life data are made at different temperatures. We agree that the individual effects of Mn and the small amounts of Zr, Ca and Al cannot be separated from the data in the alloys studied. The effect of Si on the useful life and on the structure of the oxide film is very marked in the case of the 80 Ni-20 Cr alloy. The beneficial effect of Cr is also noted.

We would like to restate our inter-

Table 6 . . . Indicating Special Significance of Alloying Elements

| Group | Useful Life at | | Alloy Analysis | | | | | Oxide Films at 950°C | | |
|-------|----------------|-----|----------------|------|-----|-----|--------|----------------------|---|------------|
| | °C | Hr | -46 | Cr | Si | Mn | Others | Fig | Electron Diffraction Pattern | Lines |

| | 1125 | 21 | 134 | 16.2 | | 1.7 | No | 6 | NiO.Cr ₂ O ₃ | S |

pretation of the oxidation resistance of heater alloys. We feel that the oxide film cannot be considered as a separate entity but rather in combination with the interface and the alloy itself. The processes by which oxidation occurs involve the transport of metal ions from the alloy through the interface and oxide to the surface. The rates of these processes are determined by the structure factors in the alloy, interface and oxide. We also feel that the stability of the oxide to decomposition and solid phase reactions on heating and cooling are of great importance and are not shown by a single cooling experiment.

F. E. BASH*—The work reported by the authors of this paper is very timely in view of the great demand for information leading to the development of better alloys for high temperature service. It is hoped that this work and other work now being undertaken will lead us to a better understanding of the mechanism of oxidation resistance of alloys when subjected to high temperature.

The alloys which were studied in this investigation were prepared in a laboratory high-frequency induction furnace, casting ingots weighing approximately 14 lb. These were forged and a portion rolled to 1/4 in. rod and drawn to 0.025 in. wire for life test. The other portion was rolled to strip for this electron diffraction study. Heat 13246 represents the old Nichrome LV (80Ni-20Cr). Heats 12246 and 12046 represent improvements in

Attention should be called to the life test figures given. It will be noted, for example, that Heat 12046 of Nichrome V (80Ni-20Cr) has a useful life of 157 hr at a temperature of 1175°C (2150°F). This compares with a life of 245 hr at 1125°C (2050°F) for Heat 13346 of Nichrome (60Ni-16Cr-Bal. Fe). It might be thought, in considering these figures, that the Nichrome wire had a useful life approaching that of Nichrome V. It must be understood, however, that the life of a nickel-chromium alloy wire varies as a power of the temperature. For example, 157 hr life for Nichrome V at 1175°C (2150°F) is equivalent to 450 hr at 1125°C (2050°F) for the same wire. We have found, also, that the durability of the nickel-chromium and nickel-chromium-iron alloys is affected by the size of the heat cast. The life on standard production heats of the same alloy composition is considerably higher than on that of the same alloy made in the laboratory furnace. The authors refer to a paper by H. D. Holler,* in which he noted the loss of chromium at high temperatures and the higher temperature coefficient of resistivity of the remaining wire. Due to the increased temperature coefficient, he concluded that the wattage density (and temperature) would be increased in sections of the wire where the chromium was more depleted. I should like to call attention to the effect of varying chromium content on specific resistance and temperature coefficient:

| Alloy | Spec. Resis. at 25°C | Spec. Resis. at 1177°C (2150°F) | Av. TC 27-1177°C |
|-------------|----------------------|---------------------------------|------------------|
| 80-20 Ni-Cr | 650 ohms per cmf | 700 ohms per cmf | 0.000067 |
| 85-15 Ni-Cr | 566 ohms per cmf | 612 ohms per cmf | 0.000072 |
| 90-10 Ni-Cr | 545 ohms per cmf | 585 ohms per cmf | 0.000081 |
| A Nickel | 60 ohms per cmf | 300 ohms per cmf | 0.0035 |

composition leading to the present Nichrome V (80Ni-20Cr). In the same way, Heats 13446 and 12646 represent the progress of development of Nichrome (60Ni-16Cr-Bal. Fe).

It will be noted from the above that the cold resistance of the nickel-chromium alloys is reduced considerably with re-

* Preprint 9207, Oct. 1947, of the Electro-Chem. Soc., "Observations on the Failure of 80 Nickel-20 Chromium Alloy at Excessive Temperatures."

* American Cyanamid Co.

* Driver-Harris Co.

duction of chromium content. It should be noted that the hot resistance also is reduced. The temperature coefficient increases rather slowly with decrease of chromium from 20 to 10 pct. The temperature coefficient of the pure nickel is, of course, very much higher. In view of this information, it is obvious that any areas which may have lost more chromium than the *average* for the wire would not have a greater wattage density (I^2R), since the specific resistance at this point would be lower than the average. Eventually the sectional area reduces more at one point than at others for reasons unknown, and the wattage density increases at this point causing failure of the wire.

I should also like to call attention to an article by A. H. Sully, entitled "A Simple Method for the Study of Metallic Diffusion in Certain Binary Alloys Systems."^{*} Sully determined the concentration gradient of chromium in an 80Ni-20Cr wire 0.021 in. diam after having been at high temperature for a period of time. He combined electrolytic etching techniques with X ray diffraction and thus obtained the chromium content at the surface of the wire and at various depths. He showed the center of the wire to have the original composition, or thereabouts, while the chromium at the surface had decreased to approximately 8 pct. The work of Holler confirms the loss of chromium in prolonged heating of nickel-chromium alloys.

C. L. GUETTEL†—I wish to ask a question concerning the nature of the reaction $2Cr + 3NiO \rightleftharpoons Cr_2O_3 + 3Ni$, involving sample 12046, the new Nichrome V. The paper states that this reaction is probable "since Cr_2O_3 is observed both by reflection and transmission above 600°C." However, what becomes of the reaction product, 3Ni? Even if this resulting nickel were immediately oxidized, why would not the NiO be found either in the outer film or next lower oxide layer? Your previous paper states that a spectrochemical analysis failed to detect nickel in the electrolytically removed film.¹² Thus, considering the latter, would not the reaction, $2Cr + \frac{3}{2}O_2 \rightleftharpoons Cr_2O_3$ be more probable?

E. A. GULBRANSEN—I think that both the direct oxidation reaction $2Cr + \frac{3}{2}O_2 \rightleftharpoons Cr_2O_3$ and the solid phase reaction $2Cr + 3NiO \rightleftharpoons Cr_2O_3 + 3Ni$ contribute to the formation of Cr_2O_3 in the film. The Ni ion in the latter reaction diffuses back to the metal. Eventually as the Cr is depleted in the surface of the metal NiO may form at the metal oxide interface. We have confirmed, by X ray diffraction studies of the same alloys, the fact that Ni is not observed in the films at least during the early periods of the reaction.

C. L. GUETTEL—During the discussion period following the presentation of your papers at the AIME meeting of Nov. 1946, I suggested the possibility that a difference in results may occur if the sample were heated electrically instead of by radiation. (My remarks incorrectly were attributed to Dr. C. G. Goetzel). Sully's work on an 0.021 in. 80 pct Ni, 20 pct Cr wire, to which Mr. Bash has already referred, shows that after prolonged heating at high temperature, the remaining metal core nearest to the oxide layer is the most depleted in chromium. The rate and direction of further atom diffusion may be affected in a different manner when an electric current passes through such a core than when the core is heated by radiation. Also, radiation heating places the source of heat on the atmosphere side of the oxide. And electrical heating, in effect, places the heat source on the metal side of the oxide. In view of these comments and the fact that, in actual use, furnace and appliance elements are heated electrically in air, I would like to suggest the following investigation based on the work of Sully and the authors of this paper: Mount and start 16 samples of the same spool of Nichrome V (of known analysis and physical properties) according to the ASTM "Standard Method of Accelerated Life Test for Metallic Materials for Electrical Heating."¹³ After one hour, subject two of the samples to the following tests:

1. A temperature determination.
2. A hot resistance determination.
3. A cold resistance determination.
4. Electron diffraction, reflection technique, to determine the identity of the surface oxide.
5. Electron diffraction, transmission technique as applied to the electrolytically removed oxide layer to identify the oxides occurring on the outer surface and in the body of the oxides.

6. X ray diffraction, applied to the remaining metal conductor in conjunction with the electrolytic etching of successive metal layers from the core according to the method of Sully, to determine the transverse chromium distribution at this specific time period.

7. Metallographic examination, transverse and longitudinal sections, to determine the degree and direction of the oxidation.

Repeat the above for other pairs of samples at suitable intervals during the life test. Apply 4, 5, 6, and 7 to the last pair after total life near the point of burnout. It does not appear necessary that 4, 5 or 6 would have to be applied to any sample when heated, as it is unlikely that different oxides would exist at an elevated temperature than when cool, after subjecting each sample to hundreds of two minute heating and cooling cycles prior to the diffraction tests (the one hour samples excepted).

Such a series of tests could relate the formation of the specific oxides with the chromium distribution in the remaining metal core at various time intervals under the standard conditions of the A.S.T.M. life test, and would be supplemented by metallographic information, and thermal and resistance measurements. The same series of tests could be applied to the older types of Nichrome V (80Ni-20Cr) and to experimental modifications of the same alloy. The application of the tests to Nichrome (60Ni-16 Cr-Bal. Fe) would depend on the adaptability of the Sully technique to tertiary alloys.

E. A. GULBRANSEN—Mr. Guettel has outlined a very ambitious program and I think a very good one. We have been doing some thinking along this line but we are not in the position to carry out such a program. We are arranging to make an X ray diffraction study of a number of heater alloys in the following manner: The specimen will be alternately heated and cooled following the ASTM life test procedures. X ray diffraction patterns will be taken of the sample only while the sample is hot. This will be done several times during the life of the specimen. This can be carried out by opening and closing suitable shutters on the X ray tube. A series of patterns also could be taken during the cold cycle of the test. A comparison of the hot and cold pictures as a function of the oxidation may add much useful information to structural changes in the metal and oxide film.

The Sully technique also appears to be a very useful method for studying the change in composition of the metal surface as a result of oxidation.

J. H. SCAFF*—I would like to ask the author if it is safe to assume that the composition of the oxide films produced at pressures of 0.1 mm of oxygen would be the same as those oxidized at pressures corresponding to the oxygen pressure of the atmosphere.

E. A. GULBRANSEN—The pressure of 1.0 mm of oxygen is chosen as a matter of convenience in evacuating the camera. In the case of nickel we do not anticipate any change in the structure of the oxide films due to the low pressure. This follows from the fact that NiO is the only oxide ever observed over the temperature range in any work known to us. One point should be carefully noted and that concerns the decomposition of NiO to the metal. If high enough temperatures are reached NiO may not form at 1 mm of O_2 while it would form in higher oxygen pressure atmospheres.

J. T. MILEK†—I wish to give my compliments to the authors for their valuable contribution.

I recall some years ago reading Professor Winchell's work on spinels. It seems

* *Jnl. of Scient. Instr.*, p. 244, Dec. 1945.

† Babcock and Wilcox Co.

to me that nickel oxide and chromium oxide form a continuous series of solid solutions in which one would have variable nickel oxide and chromium oxide contents and this should show up in the X ray data. I have not read the paper, and I apologize for that, but I wish the authors would comment on the continuous series of solid solutions and also the replacement of the bivalent end of the spinel.

For example, $\text{NiO} \cdot \text{Cr}_2\text{O}_3$ —the NiO can be replaced by MnO or MgO , and likewise the trivalent oxide can be replaced by some other oxide as B_2O_3 .

Have the authors tried an atmosphere of hydrogen sulphide and what kind of pattern is obtained in a sulphur dioxide

atmosphere?

E. A. GULBRANSEN—I failed to mention the problems one encounters in determining the crystal structure of the oxides on the surface. Some of these problems we have mentioned in previous publications. One has the problem of solid solutions of one oxide in another as well as the formation of the spinel structure. The spinel system as Mr. Milek mentioned is a very flexible one in which various oxides can fit. This represents the main difficulty in completely specifying the composition of the oxide. Both X ray and electron diffractions indicate only the lattice spacings and give no direct information about what atoms are in the crystal. The spinels represent a wide

variety of oxides which give similar parameters for the common metals used in heater alloys.

To answer your other question, we have not tried atmospheres containing hydrogen sulphide or sulphur dioxide. We have not made such experiments and I would prefer not to comment until we have done so.

An Electron Diffraction Study of Oxide Films Formed on Copper-nickel Alloys at Elevated Temperatures

By J. W. HICKMAN, Member AIME, and E. A. GULBRANSEN

DISCUSSION

(R. Smoluchowski and M. L. Fuller presiding)

J. T. MILEK*—I wonder if Dr. Gulbransen is justified in using the equilibrium constant as a criterion for evaluating which oxide will form. I think, thermodynamically, it is better to use the free energy of formation in his calculations rather than the equilibrium

constant and to determine how the free energy of formation varies with the temperature. These thermodynamic relationships might explain in a more logical way why a certain oxide will form in preference to some other oxide than can be explained by the equilibrium constant relationship.

E. A. GULBRANSEN (authors' reply)—The free energy ΔF and the equilibrium constant K are related by the equation

$$\frac{-\Delta F}{2.3 RT} = \log K$$

It does not make any difference which you use in discussing equilibria.

G. V. PORTER*—At what composition of copper and nickel are there enough electrons contributed by copper to fill the d band of the alloy? You have not mentioned in your talk at what combination this occurs.

E. A. GULBRANSEN—The composition is 40 at. pct nickel.

Decarburization of Chrome Nickel Alloys by Their Surface Oxides in High Vacua and at Elevated Temperatures

By E. A. GULBRANSEN, W. S. WYSONG, and K. ANDREW

DISCUSSION

(R. Smoluchowski and M. L. Fuller, presiding)

E. N. SKINNER*—In this paper, Dr. Gulbransen and his associates have employed their usual beautiful experimental techniques to offer a fundamental contribution to our meager knowledge of high temperature gas-metal equilibria.

* The International Nickel Co., Inc.

Although the procedures adopted in this work are above reproach, there are several questions which might be raised concerning the interpretation of the data.

It has been considered that all carbon in the three heater-type alloys studied has been entirely in solid solution within 700–910°C, the range of temperatures investigated. This assumption is not consistent with observed micro-structural

changes occurring in carbon-containing Ni-Cr and Ni-Cr-Fe alloys. The solid solubility of carbon in alloys of this type is not definitely known but is conceded to be extremely low. For example, carbide inclusions have been noted after appropriate heat treatment at 450°C in an alloy of 15 Cr, 6 Fe, balance Ni which contained the uncommonly low carbon content of 0.02 pct. A similar base com-

position containing 0.04 pct will exhibit an unmistakable precipitate of carbide after heating the solution-treated alloy for two hours at 875°C. It is therefore highly probable that the 80/20 and 62/16 samples, containing carbon levels of 0.08, 0.12, and 0.06 respectively, consisted of a carbide-studded matrix at the temperature of testing.

If the ribbon upon which the present work was conducted was in the soft condition, this strand-annealing operation probably consisted of rapid cooling from temperatures at or above 1100°C. Subsequent heating to temperatures in the range of 700–910°C after this solution-anneal would be expected to promote the precipitation of carbides preferentially in the grain boundaries. Assuming that this condition existed, the two rates of decarburization noted by the authors might conceivably be explained by a rapid rate of outward migration to the oxide interface by the carbon atoms located in the grain boundaries and along slip and twinning planes and a slower

rate of migration through the lattice.

In comparing the decarburization by high vacua vs. hydrogen, we are interested in learning whether the loss in weight of the specimen was appreciably affected by the dissociation of NiO in the Ni-Cr spinel or by loss of residual constituents such as Ca, Zr, Al, Mg, or Si.

E. A. GULBRANSEN and K. ANDREW (authors' reply)—We are in complete agreement with Dr. Skinner about the presence of carbides in the chrome-nickel alloys. This should have been made clearer in our paper. In order to calculate the equilibria of carbon and the oxides in the film it is necessary to assume that the carbon is in solid solution since the thermodynamics of the carbides at the temperatures under discussion is not known. The equilibria calculated with this assumption is an estimate of the actual equilibria which must involve the carbides.

Dr. Skinner has suggested an alternative explanation of the two rates of decarburization noted in the experiments.

There is one fact which is in opposition to the mechanism proposed, namely, the second rate is observed after the surface oxide film has been removed. We feel that we are dealing with a reaction between carbon, which is in a large excess in most of the experiments, and two different sources of oxide, the surface oxide reaction with carbon being the more rapid reaction. Such an explanation overcomes the objection noted above.

We have not studied the loss in weight due to dissociation of NiO or loss of residual constituents such as Ca, Zr, Mg, Al or Si.

M. LACHANCE*—Has any conclusion been drawn regarding varied silicon content in an alloy as it affects the decarburized weight losses observed?

E. A. GULBRANSEN and K. ANDREW—We have not studied the decarburization rates as a function of the silicon content in the chrome-nickel series of alloys.

Fractographic Study of Cast Molybdenum

By C. A. ZAPFFE, Member AIME, F. K. LANDGRAF and C. O. WORDEN

DISCUSSION

(D. L. Martin and J. E. Burke, presiding)

H. S. AVERY*—Would you comment on the type of illumination that you use to give the depth of focus in your high magnification photographs?

C. A. ZAPFFE (authors' reply)—In fractography, depth of focus or at least an illusion of depth of focus, is attained by oblique lighting, which serves much as the etch does on polished samples to improve the pattern by varying the reflection from grain to grain. Cleavage facets may be studied visually without oblique illumination, but for photography it is essential.

H. S. AVERY—With your oblique lighting do you use a conventional vertical illumination or dark field illumination?

C. A. ZAPFFE—We have tried both, and by far prefer the conventional vertical illumination. Polarized and other types of illumination, such as "sensitive tint," can also be used. There is no special restriction.

J. H. BOSS*—What kind of microscope do you use?

C. A. ZAPFFE—We used a Bausch and Lomb MILS for this work but have used Zeiss, Leitz, and others. There is no special restriction in type of microscope, except that obliquing has an exaggerated importance.

C. W. HORSTING†—Do you use anything else besides the carbide to deoxidize the molybdenum?

C. A. ZAPFFE—Other deoxidizers

could undoubtedly be used, but carbon has the feature of forming a gaseous deoxidation product which can be removed from the system under the conditions of the vacuum.

F. R. MORRAL*—I read this paper with interest. The authors should be congratulated for the interesting and clear fractographs. I note that on p. 3 of their paper only one molybdenum carbide is discussed although there is a possibility that two are present in the MoC diagram as shown by Sykes in the 1948 ASM handbook, p. 1183. I wonder if the MoC would be one of the two discussed in item 4 under the conclusions on p. 21 of the paper.

C. A. ZAPFFE—Professor Morral raises a good point with regard to MoC, which we are glad to accept as he suggests.

Effect of Composition on Grain Growth in Aluminum-magnesium Solid Solutions

By LOUIS J. DEMER, Junior Member, and PAUL A. BECK, Member AIME

DISCUSSION

(D. L. Martin and J. E. Burke, presiding)

C. G. DUNN*—May we have more detail on the time required for recrystallization? How did you determine when recrystallization was complete?

L. S. DEMER (authors' reply)—In order to determine the point of complete recrystallization, the specimens of material were annealed for various periods of time and their hardness values were determined. Then hardness was plotted vs. the time, both to logarithm scales, and it was found that when the recrystallization was not complete, the points fell on a line which had a slope. When recrystallization was complete, specimens annealed for longer periods of time fell on the horizontal line. We took the point of complete recrystallization to be the juncture of these two lines.

C. G. DUNN—The break in the hardness-time curve probably does mean something. On the other hand, it is possible to have recovery of physical properties prior to recrystallization. In other words, the metal may soften without any appreciable recrystallization actually occurring. Furthermore, as grain size increases, there may also be a softening from this source. I am not too familiar with the application of hardness tests to the determination of the course of recrystallization and therefore want the authors' views on the reliability of this method.

L. J. DEMER—This was the method of determining the point of complete recrystallization. Then it was checked by examining the specimens microscopically and those points were taken as points of complete recrystallization.

C. G. DUNN—To make a contrast on the reliability of the hardness test, I would say it does not apply to large grains or single grains of silicon ferrite. For example, we have observed on the basis of a Knoop Hardness test complete softening prior to recrystallization. Therefore, the hardness test may, in my opinion, introduce undesirable complexities into the study of the extent of recrystallization.

P. A. BECK (authors' reply)—We made some X ray diffraction patterns for the aluminum-magnesium alloys, as well as for pure aluminum, and the X ray method confirmed the hardness method

as to the time necessary for complete recrystallization.

C. G. DUNN—Concerning another point brought out by the authors I would like more information on the effect of the second phase on the recrystallization process. Your data show a smaller grain size as well as longer time for complete recrystallization with the 2 pct Mg alloy. Unless the induction period is considerably lengthened by the second phase, these two facts would indicate a slower grain boundary movement in the presence of a second phase. As I understand it, the main driving force for recrystallization is internal strain energy. We have here then a grain boundary moving in the presence of a second phase but under the action of strain energy. Could the action of the second phase be discussed further?

P. A. BECK—To my knowledge, no complete analysis has as yet been made of the effect of a dispersed second phase on the two rates pertinent to recrystallization, namely the rate of nucleation and the rate of growth. However, it seems very likely that the main effect of a dispersed second phase in decreasing the rate of recrystallization is exerted through decreasing the rate of growth of the new grains, rather than through an effect on the rate of nucleation.⁷

J. E. BURKE—Would it not develop that all of the observations could be explained by saying that the rate of nucleation was constant but that the rate of nucleus growth had been decreased?

P. A. BECK—Yes, at least qualitatively.

C. G. DUNN—I would like to make one more comment on growth in a strained matrix because the following paper by Professor Beck and coworkers will have more on growth presumably in the absence of strain. If true nucleation occurs, new surfaces are developed and energy is required for this. As long as the matrix is in a strained condition the energy needed for nucleation and growth may be obtained from the matrix. If deformed grains instead of nuclei grow in the strained matrix, the picture is different.

J. E. BURKE—Anderson and Mehl⁸ made an observation that is possibly pertinent to this paper. They found that the rate of nucleus growth during recrystallization increased with decreasing

grain size of the deformed material. That is, the rate of nucleus growth is greater in an originally fine grained specimen than in a coarse grained specimen, even though the two specimens were deformed by identical amounts. This could indicate that interfacial energy as well as deformational energy, is important in controlling the rate of growth of recrystallization nuclei.

P. A. BECK—I think that there is a more likely explanation of that phenomenon. The fine grained material, when cold worked to the same reduction of area, develops considerably higher hardness than coarse grained material. Thus, in spite of the same geometry, the effective cold work is greater. This accounts for the higher rate of recrystallization.

D. C. JILLSON*—I believe that only one set of fabricating conditions was studied, ending with a final cold reduction of 33 pct. Since changes in fabricating conditions might be expected to affect recrystallization phenomena, and hence might alter some of the conclusions, it might be well to state this limitation in the conclusions.

P. A. BECK—The conclusions are meant to apply under the conditions of the experiments, as fully described under "Experimental Procedure." It appears somewhat impracticable to repeat all those conditions in the "Conclusions."

J. E. BURKE—I have two questions I should like to have the authors comment upon. First, what is the influence of magnesium content upon the average rate of grain growth? The second question concerns the activation energy for recrystallization. Anderson and Mehl reported values ranging from 64,500 cal per mol to 52,100 cal per mol for elongations of from 5 to 15 pct. The present authors report a value of 44,000 cal per mol for a deformation of 33 pct. The range of values encountered serves to emphasize the uncertainty of the physical meaning of the computed "heats of activation." It would seem probable that the change in temperature dependence indicates a change in the atomic mechanism occurring during recrystallization.

The differences in the amount of deformation can account for only a few calories per mole in residual energy left

- x Overall activation energy for complete recrystallization. (Calvet, Trillat and Paic)⁹

in the metal, and thus cannot account for the difference of several thousand calories per mole in the apparent heat of activation.

P. A. BECK—Concerning Dr. Burke's first question, I should like to refer to Fig 14 and 16 of Ref 1. It is shown there that at small grain sizes the in-

stantaneous rate of growth $\frac{dD}{dt}$ is higher for pure aluminum than for the 2 pct Mg alloy. However, in pure aluminum the rate decreases faster than in the alloy, so that eventually the relative rates are reversed. After about 4300 min. at 400°C, the grain size in the Al + 2 pct Mg alloy

was larger, in spite of a smaller grain size, as recrystallized.

Dr. Burke observed the difference between the heat of activation values reported by us on the one hand and by Anderson and Mehl on the other for the recrystallization of pure aluminum. He concluded that this difference emphasizes the uncertainty of the physical meaning of the computed heats of activation. He has, however, neglected to consider the fact clearly shown by Anderson and Mehl, that the Q values for both the rate of nucleation and the rate of growth decrease with increasing prior deformation. Fig 16 shows the data from Fig 23 of Anderson and Mehl's paper,⁸ and dotted lines indicate the extrapolation of their curves for higher deformation values. Since in our work the two factors, nucleation and growth, were not separated, the heat of activation for the overall process of recrystallization may be expected to lie in between the two extrapolated curves. As seen in Fig 16, this condition is well satisfied, regardless of the uncertainty of extrapolation. The Q value estimated from older data of Calvet, Trillat and Paic⁹ for 95 pct deformation also falls between the reasonably extrapolated lines. Far from agreeing with Dr. Burke, we feel justified in concluding that, as far as comparisons can be made at all, the data shown in Fig 16 are indeed quite consistent with each other.

Effect of a Dispersed Phase on Grain Growth in Al-Mn Alloys

By P. A. BECK, Member AIME, M. L. HOLZWORTH and P. SPERRY

DISCUSSION

(D. L. Martin and J. E. Burke, presiding)

J. S. SMART, JR.*—From the data presented by the authors, it appears plausible to speculate on the possibility of the existence of a size factor which governs the effectiveness of the precipitated particles in inhibiting grain growth. For instance, the 650° curve of Fig 4 indicates that sufficient precipitate was dissolved in one minute at temperature to remove the inhibiting effect completely.

However, the authors noted that the precipitate did not completely dissolve in such short time, but in fact, required something under 125 min. to reach a sub-microscopic stage. This behavior seems to indicate that the inhibiting effect is due primarily to particles of very small size which would dissolve rapidly at sufficiently high temperature. If so, it can be readily understood why this curve approximates the behavior of a solid solution alloy despite the presence of the remaining precipitated particles of large size during the whole of the straight

section of the curve. Furthermore, this mechanism would explain why the inhibiting effect is strong even though very little visible precipitate is present, as the authors have found elsewhere.

If this reasoning is extended further, the "incubation period" at low annealing temperatures would appear to be the time required for sufficient coalescence to take place to allow the small and effective particles to grow to an innocuous size. At higher annealing temperatures, the incubation period might then depend on a combination of the rates of solution and coalescence of the particles. The apparent anomaly that specimens containing large amounts of manganese

* American Smelting and Refining Co.

compound should have shorter incubation periods, as noted by the authors on p. 14 of the paper, would thus be explainable on the basis that they were in a more advanced stage of coalescence to begin with, and therefore required a shorter period for the coalescence to continue beyond the critical size range.

The interpretation placed by the authors on the experiments to investigate the effect of various degrees of deformation ascribes a very considerable effect to various degrees of prior reduction. However, from Table 7, it is evident that the process annealing procedure varied from 5 min. at 530°C for the samples reduced 90 pct to 65 min. at 530°C for those rolled 20 pct. This treatment would therefore have resulted in increasing amounts of precipitated compound in the specimens of descending order of reduction. Since the final anneal was at 625°C, which is very close to the solvus point for the alloy used, it does not appear strange to find that the specimens which have the greatest reductions, and the least precipitated compound, lose their restricted status the earliest, as the precipitate dissolves. Is it therefore not unlikely that the differences in process annealing are significant and should be included with differences in reduction in any explanation of the behavior shown in Fig 13 and 14?

P. A. BECK (authors' reply)—Mr. Smart noted the initial slope of the 650°C line for the 1.1 pct Mn alloy in Fig 4 of the paper is approximately equal to the slope for high purity aluminum, as extrapolated to the same temperature from Fig 6 of Ref. 36. From this fact he concluded that in the Mn alloy "sufficient precipitate was dissolved in one minute at temperature to remove the inhibiting effect completely," even though compound particles were found microscopically after much longer periods of annealing. This conclusion is based on the idea that the slope of the $\log D$ vs. $\log t$ line represents the rate of growth. However, as described on p. 10 of Ref. 36, this is not the case. For any value of D , the instantaneous rate of growth $\frac{dD}{dt}$ depends on the parameter K as well as on the slope n . If a grain growth line is obtained for high purity aluminum at 650°C by extrapolation from Fig 5 of Ref. 36, it is easily seen, by comparison with the 650°C line of Fig 4 of the present paper, that actually the instantaneous rate of growth for high purity aluminum is about 200 times larger than that for the alloy, compared at the same grain size. This suggests that the manganese compound particles seen under the microscope are in fact very effective in reducing the rate of growth. There appears to be at present little basis for the suggestion that the inhibiting effect is due primarily to particles of very small size. Actually, it is expected that any difference in inhibiting effectiveness that may be ultimately

traced back to a particle size effect, would turn out to be rather small. Every indication points to the fact that it is the total number of dispersed second phase particles that primarily determines the effectiveness of inhibition. It is, of course, obvious that if the same total amount of precipitate is present in the form of smaller particles, the effect is larger, simply because the number of particles is then larger.

Mr. Smart is correct in observing that the series of specimens in Table 7, prepared for the study of the effect of increasing prior deformation, did not receive identical processing. The situation was, however, not nearly as unfavorable as it appears from consulting Table 7 only. As shown in Table 3, the treatment previous to the varying 530°C anneals of Table 7 was a series of anneals at 550 and 530°C common to all specimens. As a result, the differences in processing the specimens of series C, D, E, F and G, had no significant effect on their coarsening characteristics. This was also shown in a later experiment, not included in the present paper, where the attempt to finish with the same specimen thickness was given up, and instead the processing treatment was kept constant. In this experiment the decrease of the incubation period with increasing reduction by rolling was confirmed.

C. G. DUNN*—I want to congratulate the authors on their excellent results. They certainly are adding fundamental knowledge to grain growth processes, and this we need. The effect of dispersed phases is particularly important, I think. Using the authors' term "coarsening," it perhaps should be mentioned that phenomena other than the effect of a dispersed phase can be associated with coarsening, particularly in fine grained materials where textures play an important role. Would the authors care to say something on this aspect of coarsening?

P. A. BECK—Dr. Dunn, knowing about our latest results, is offering us here a welcome opportunity for presenting them in this discussion.

Cook and Macquairie⁴⁴ showed that in tough pitch copper two different types of coarsening may occur. The one type, which they produced by annealing at 750 to 850°C, after about 50 pct reduction by cross rolling, did not occur in oxygen-free varieties of copper. It was recently found⁴⁶ that this type of coarsening, which is characterized by fairly round coarse grains with irregular, "ragged" boundaries and small, completely enclosed twins (Fig 31), may be obtained in tough pitch copper after straight rolling, as well as cross rolling. It appears very likely that this type of coarsening depends on the presence of finely dispersed Cu₂O particles in the copper, and that it is, therefore, closely related to the

coarsening phenomena in Al-Mn alloys, described in the paper. The term "random coarsening" used in the introduction of the paper, is descriptive only in the sense that these coarse grains may lack any preferred orientation, and that this type of coarsening does not depend on the presence of a texture in the fine grained recrystallized matrix. However, as shown by Bowles and Boas⁴⁶ in a paper published after the present paper was submitted for publication, it is possible for the coarse grains growing in commercial aluminum (which contains dispersed phases) to possess a preferred orientation. For this reason it now seems preferable to describe this coarsening as "inhibition-dependent" rather than "random."

The other type of coarsening in copper found by Cook and Macquairie, and before them by Dahl and Pawlek,²⁹ does not require Cu₂O particles. It may occur in oxygen-free copper as well as in tough pitch copper. What it does require, is a well-developed "cube texture" in the matrix, as recrystallized. In the presence of such a sharply defined texture the small recrystallized grains, most of which have fairly closely the same orientation, show great reluctance to undergo gradual grain growth. Copper with the "cube texture" remains quite fine grained up to high temperatures. Finally at about 1000°C (or at a lower temperature after a longer period of annealing) it abruptly develops very large grains. Fig 32 shows such grains embedded in the fine grained matrix in which they grew. Typical of the coarse grains of this type is the presence of very long, straight twin boundaries, inclined at about 45° to the direction of rolling (Fig 33). These coarse grains have a well-developed preferred orientation, different from that of the fine grained matrix. The orientation relationships were recently studied by Bowles and Boas.⁴⁶ It was recently found at this laboratory that, even in high purity aluminum, gradual grain growth was practically prevented in the presence of a very sharply defined texture,⁴⁷ regardless of the orientation with respect to the rolling direction. Apparently, the determining factor here is the similarity of the orientation of neighboring grains of the fine grained recrystallized matrix. When high purity aluminum with such a structure is annealed long enough at 500–600°C, abrupt coarsening sets in. Grains many times larger than the specimen thickness may be obtained by this mechanism.

The views expressed in the introduction of the present paper are thus confirmed: there are at least two different types of coarsening, the one depending on a dispersed second phase, the other on the presence of a very well developed texture. The common feature of both types of coarsening is the suppression of the continuous or gradual type of grain growth and the abrupt development of extremely large grains which grow by feeding

directly on the fine grained matrix.

C. S. SMITH*—It is, perhaps, somewhat undesirable to use the term "attraction," as do the authors on p. 25 of their paper, for the interaction between the grain boundary and a particle of the second phase. Surely, though a boundary will cling to an inclusion once it has met it, and can be retained in positions that involve considerable curvature, it will not be influenced by an inclusion at a distance.

The effectiveness of such an anchor is relatively little dependent on the surface energy of the inclusion. It is essentially a question of geometry, for the numerical value of the interfacial tension of the boundary cancels out, being both the force for driving and for restraint. If the second phase is not rigid, it will become lenticulate in shape under the influence

of the triangle of surface forces around its edge, but such departures from a spherical shape will increase the length of the line of contact, and hence the restraining force, by factors of not more than two or three except when the dihedral angle approximates zero and the second phase spreads as a film separating the grains.

I have come to believe strongly in the simple geometric theory of grain growth, first clearly enunciated by Harker and Parker. The initial contact between grains will produce a random network of surfaces and points of contact. Each internal intersection must involve three grain boundary surfaces meeting along a line and six grain boundaries (and four edges shared with four grains) meeting at each point. If all surfaces exert the same surface tension they will tend to establish angles of 120° with each other and the edges will tend toward the stable "tetrahedral" angle of $109^\circ 20'$ with each other.

Except with ideal stacking of minimum-area tetrakaidecahedra (the three-dimensional equivalent of hexagons), curvatures are inevitably introduced to reconcile the required angles with the random points of contact and this introduces instability. The surfaces will then tend to move toward their centers of curvature, allowing further continual readjustment of the edges. This will proceed smoothly (at a rate dependent on the temperature and the local curvature) until more than three surfaces meet together at an edge or more than four edges meet at a point. The moment this happens the system becomes locally highly unstable and the surfaces will rapidly assume new positions of local equilibrium. Occasionally there will be formed tetrahedral grains, all of whose sides are convex and therefore bound to move inwards, bringing the points of contact with the four neighboring grains together in a stable balance as the grain disappears. Only as this happens will the number of grains decrease or the average grain size increase. This is illustrated two-dimensionally by the accompanying figures. The boundaries of the five-sided and four-sided grains shown in Fig 34A will move progressively toward their centers of curvature through the positions shown by the dotted line, to reach eventually approximately the configuration shown in the solid lines of Fig 34B. If the surfaces are all of equal energy, the moment four of them meet they become highly unstable, for, in place of the original six equilibrium angles of 120° , there are now two angles of 120° and two of 60° . The slightest disturbance will cause the films to seek new equilibrium with a new interface forming at approximately 90° to the one that has disappeared, and there will be accompanying readjustments throughout, as shown by the dotted lines in Fig 34B. The net result is that the five- and four-

* University of Chicago.

sided grains have become respectively four- and three-sided, with the addition of one side to each of two neighboring grains. The three-sided grain can now disappear completely by its sides moving toward their centers of curvature without any further instability occurring.

If something should happen to render the intersection of four surfaces or five edges stable, further grain growth could not take place. The situation that normally is followed by the most rapid motion now constitutes a complete block. Such an obstacle can be caused either by inclusions (where the requirement is only that all boundaries meet its surface at 90°) or by the grain boundary energy differing from boundary to boundary. In a single-phase alloy, although the energy is clearly not highly sensitive to orientation over most of the range of mismatch, it is likely—in fact, the recent experiments of Dr. C. G. Dunn make it certain—that in the range of slight mismatch there is a high dependence on orientation. Consider the grains shown in Fig 34B with the four interfaces momentarily meeting at a point. This is unstable if the four interfaces and the new interface that must be produced all have equal energies. If, on the other hand, the new interface (the horizontal one in the figure) should have a higher interfacial tension than the resultant of the other four tensions in its direction (that is, if it has a value greater than the diagonal of the polygon of forces they produce) the four films will be quite stable in contact with each other, unless and until movement of other parts of the boundary allows changes of the local angles to such an extent that the above criterion is no longer true. Such four-grain corners are frequently seen in two-phase structures (for example in the case of alpha-beta brass, where the grain boundary between two alpha grains has about 1.3 times the energy of the other possible interfaces) and it can occasionally be found in normal single-phase polycrystalline metals, particularly if the metal possesses a high degree of preferred orientation. The formation of these stable points can completely stop grain growth unless the grain size is extremely small and the curvatures high. Such a blocked network of grain boundaries will be quite stable on indefinite annealing unless some other action sets in to release it, whereupon—if it occurs locally—one grain may become much larger than its neighbors and continue to grow, for a former block will no longer be effective against the new, high, local curvatures. This sudden removal of a block could occur if it were possible for grains to change their orientation under the influence of surface forces (or if orientation changes as a result of local plastic deformation or new nucleus formation), with resultant change of interface energy and upsetting of the local force-polygon. If blocking is due to inclusions, the solution of the finest par-

ticles would have a similar effect. In either case, some grains would become considerably larger than their neighbors, the effective negative curvature of their boundaries larger, and thereafter their boundaries would progress continually and at a more or less constant rate into the network of smaller grains in which motion remains blocked. This will continue until the growing grain encounters another one of the same type. The frequency of nucleation will determine whether the grains are only a little larger, as in the case of abnormal grain growth in steels, or enormously larger, as in the general case of "secondary recrystallization."

In addition to blocking at a point by inclusions or by the necessity for the formation of a high-energy interface, it is also possible for a grain boundary to be blocked away from an intersection by inclusions, or by surface forces alone if the boundary, moving toward its equilibrium position, has to change its angle and pass through a minimum energy direction in relation to the two lattices that it divides. Unless the curvature is great enough to overcome this, the boundary will have a definite tendency to "hang" along certain preferred directions between the two crystals. In practice it is probable that the stopping of grain growth is due to a combination of all these factors. It does seem to be a fact that "secondary recrystallization" occurs only in material that has substantially ceased growing in the normal fashion. It is an interesting speculation as to whether primary recrystallization is also a result of a somewhat similar reaction taking place in a much finer network of interfaces.

Although a phenomenon as complex as grain growth clearly cannot be the result of a simple system of causes, it is nevertheless possible to account for many of the observations on the simple basis of the geometry that would result from various interfaces interacting in accordance with the principles enunciated by Plateau, Gibbs, and others in the nineteenth century.

P. A. BECK—Dr. Smith's interesting contribution to the discussion is much appreciated. In the absence of plastic deformation, grain boundary migration in pure metals, resulting in a gradual increase in the average grain size, is undoubtedly motivated by the interfacial tension connected with the grain boundaries. This view was clearly expressed by H. Althertum⁴⁸ about 25 years ago. The detailed theory of the geometry of grain boundary migration, as stated by Dr. Smith, was developed more recently by Harker and Parker.⁴⁹ Although the latter authors used an atomistic terminology, it has been certainly quite clear that they investigated the behavior of grain boundaries in single phase metals under the influence of what is phenomenologi-

FIG 34—Tracings of soap bubbles illustrating idealized shapes and adjustment of grain boundaries moving under the influence of surface tension.

cally described as surface tension forces. Their considerations are, in the main, doubtless correct, but require two corrections. First, the relative lattice orientation of neighboring grains affects the value of the interfacial tension.⁵⁰ This brings about large deviations of the equilibrium dihedral angles from 120°, depending on the orientation. Also, it is becoming increasingly clear that the simple surface-tension theory of grain growth needs to be completed by consideration of the effects of orientation, probably even beyond those just mentioned. Secondly, although the grain boundary movements serve the tendency to approximate equilibrium angles and straight boundary surfaces, the deviations and irregularities are nevertheless self-perpetuating. Stable grain boundary geometry is thus not actually reached through grain growth, as was originally postulated by Harker and Parker. It was clearly shown by recent isothermal grain growth studies with high purity aluminum³⁶ that grain growth continues until stopped by the outside surfaces of the specimen.

It is gratifying that Dr. Smith agrees with the view set forth in the present paper, that coarsening is motivated by essentially the same forces that produce gradual grain growth. Whether the coarsening results in the formation of grains only ten to a hundred times larger than the fine grains of the matrix, as in steels, or 10³ to 10⁴ times larger, as it does under certain conditions in copper, the process is always actuated by surface tension, modified by the requirements of orientation. Terms like "abnormal grain

growth" and "secondary recrystallization," which were somewhat discredited by ambiguous usage, tend to confuse this picture.

As described in the paper, *inhibition-dependent coarsening* is a type of grain growth that starts at isolated points in a fine grained structure, after general gradual grain growth had been halted by the inhibitive effect of a dispersed second phase. In the examples described, the inhibition was locally overcome by the re-solution and coalescence of particles of the dispersed phase. Once a certain grain, through favorable local conditions, succeeded in growing considerably larger than its fellows, it will continue to grow with relative ease at the expense of neighboring small grains. This effect of "grain size contrast" was found long ago by Z. Jeffries.^{1,2}

It should be emphasized here that the above outlined mechanism for coarsening does not require any preferred orientation of the small grains of the matrix. Neither could it conceivably lead to a preferred orientation of the coarse grains formed from a random matrix. However, the mechanism considered may be still operative if the fine grains of the recrystallized matrix did possess a certain amount of preferred orientation. In such a case, it would be expected that all grains which happened to have local conditions of inhibition favorable for growth would not be, in general, equally likely to grow. Those having a particularly favorable orientation relative to their neighbors will be preferred. Thus the presence of a preferred orientation in the fine grained recrystallized matrix leads to a preferred orientation of the coarse grains. This condition is simply a result of the dependence of the rate of growth of a grain upon its orientation with respect to the preferred orientation of its neighbors. There is no need to assume the formation of "nuclei" of a certain orientation, or to postulate that residual portions of the deformed structure remain to serve as nuclei after surviving recrystallization, general grain growth and long periods of recovery at high temperatures.

Although preferred orientation of the coarse grains may occur in inhibition-dependent coarsening, it is by no means a necessary condition. On the other hand, in the case of *texture-dependent coarsening*, as explained above in the answer to Dr. Dunn, the fine grained recrystallized matrix *must* have a sharply defined texture in order to restrain gradual grain growth; therefore, the coarse grains growing in this highly oriented matrix have, of necessity, a preferred orientation of their own. The specific mechanism proposed by Dr. Smith for the restraint of gradual grain growth in a fine grained metal with a strong texture, is interesting. Whether or not it actually accounts for the observed facts remains to be estab-

lished by further research.

J. P. NIELSEN*—Referring to Dr. Smith's discussion on interfacial energies between grains not identically oriented, I wonder if, in the case of close-packed hexagonal metals, a new and perhaps important factor does not also enter into the picture: the difference in thermal expansion coefficients between two adjacent grains at the surface contact. Such a factor would depend of course on the increase in temperature above that at which the metal is completely relaxed.

C. G. DUNN—In the low range of orientation differences, I believe we actually need more data. This work on grain boundary surface tensions, which I hope to report at the next meeting of the Institute, actually was somewhat exploratory in nature. The groups of crystals investigated—each a three-grain group as was described in a technical note⁵¹—had crystals with a (110) plane in the plane of the sheet. The only variable, therefore, was the direction of the cube edge in the plane of the specimen.

Since the orientations were controlled, it was possible to have two grains in each three-grain group with the same difference in orientation. An arbitrary value of 15 was used. With this common orientation difference providing communication between groups, an entire range of orientation differences could be investigated.

Omitting a description of the entire curve, the shape of the curve indicated values of surface tension at orientation differences of 6 to 8° that were about one half the maximum value. The shape of the curve in this range of orientation differences is important to the understanding of strong texture materials such as copper and nickel-iron with the "cube texture." Strong texture materials should have less grain boundary energy than weak texture materials with the same average grain size.

So much for the surface tension measurements. I would like to say something about orientation relations as a factor in growth processes. First, there is the well known principle that a difference in orientation is required for growth. Secondly, certain orientation relationships, as for example twins, appear to be less favorable than other orientation relationships for growth.

With orientation relationships in mind let us consider the behavior of fine grained copper or nickel-iron with a strong cube texture. What grows in these materials by coarsening or secondary recrystallization always has an orientation which is different from that of the cube texture. Pawlek in 1935 reported that the orientation of the large grains in nickel-iron were as follows: a (120) plane in the plane of the sheet and a [001] direction parallel with the rolling direction. Similar results have been reported for

copper but there are also other textures. Omitting twin orientations (actually appreciable material is present as twins in the large grains) there are still many definite preferred orientations remaining. From symmetry they can be reduced in number and classified in relation to the cube texture. All fall 20 to 30° away from the cube texture. One orientation relationship reported recently by Bowles and Boas in Australia has a (111) plane common with the cube texture.

If we call coarsening of the grain structure, starting with a strong texture fine grain matrix, as "strong-texture dependent coarsening" in contrast to "dispersed phase inhibited coarsening," we still need another type designation to describe the case of development of the strong (110) [001] texture in silicon iron.* Unlike copper and nickel-iron, the final large grained silicon iron sheet, to which I have reference, has a strong single texture. Furthermore, the large grains do not have any unusual characteristic shapes or shapes with straight boundaries as Professor Beck pointed out is the case for oriented coarsening in copper and nickel-iron. The prior fine grained material in the as-recrystallized condition does not have a strong single texture as does the copper or nickel-iron examples but has a rather weak texture composed probably of two or more weak preferred crystal orientations. The development of large grains in silicon iron, therefore, is quite different from the development of large grains in materials having the cube texture. Nevertheless, I think it could be classified also as "texture-dependent" but certainly not as "strong-texture dependent."

P. A. BECK—Dr. Dunn's results, and his method for determining interfacial energy as a function of the relative orientation of the adjoining grains are indeed very interesting and pertinent to the questions discussed. We have also noted the fact, referred to by him, that the preferred orientation of the coarse grains usually deviates about 20 to 30° from the preferred orientation of the fine grained matrix. It would be interesting to speculate on the possible causes of preferential growth with an orientation difference of this particular range.

On the basis of information now available to us concerning the coarsening in silicon-iron, it appears that this is not of the "texture-dependent" type. It may be suspected, however, that it depends on inhibition by at least one dispersed second phase. With a complex material of commercial purity, which probably contains several dispersed phases, the exact role of each is difficult to ascertain. But it seems that the dispersed manganese sulphide, which is removed during annealing, may have an important role

*The (110) [001] texture was discussed at the 1948 ASM Symposium on "Cold Working of Metals," under the subject "Recrystallization Textures."

* College of Engineering, New York University

in the process. It was shown recently⁵² that under certain conditions nitrogen (perhaps in the form of dispersed aluminum nitride particles) may provide so much additional inhibition that coarsening is prevented altogether. The role of the much smaller amount of nitrogen normally present in silicon ferrite has not yet been clarified. Possibly, the coarsening reaction depends on the combination of two or more inhibitors, in analogy to the double inhibitor used with tungsten, as described in the Introduction of the present paper. In this connection it should be mentioned that, in the method most generally used for the manufacture of coarse grained tungsten filaments, the inhibitor used is potassium silicate. Most of this inhibitor evaporates during the first heating of the filament, while the coarse grains are formed. However, a portion of it remains in the filament. Here, too, the situation is quite similar to that described in the paper for the coarsening of Al-Mn alloys. As explained above in the answer to Dr. Smith's discussion, preferred orientation of the coarse grains may occur under conditions of inhibition-dependent coarsening, so that the phenomena in silicon-iron do not appear to necessitate a separate class of coarsening.

J. E. BURKE*—The authors have presented an excellent paper and have demonstrated very clearly the importance of growth inhibiting dispersed phase in promoting the appearance of very coarse grains. I should like to present a partial explanation of the role of the inhibiting phase. As Zener has shown, and as the authors demonstrate in this paper, there is a definite relationship between the concentration of the inhibiting constituent, and the limiting grain size, or limiting boundary curvature. Grain growth will cease when the driving force for grain growth, the curvature of the grain boundaries, is just balanced by the inhibiting effect of second phase inclusions.

Now, considering the situation in two dimensions, all grains are composed of sides and corners, and at the corners three boundaries usually meet at angles of about 120°. If all the grains have six

sides, the sides also can be flat, and as Harker and Parker⁴⁹ showed, there will be no tendency for grain growth. If the boundaries always meet at corners at angles of 120°, the curvature of the faces will increase as the number of sides on a grain increases, being concave outwards for more sides than six and concave inwards for less sides than six. In a reasonably uniform aggregate of grains, the number of sides on grains will vary from three to about eight or nine. In these cases, no very large curvatures are encountered. If now, due to some fluctuation, a much larger grain is produced, it will have many sides, being bounded by small grains. These sides will have more pronounced curvatures than those of more or less uniform grains. Thus, the amount of second phase impurity that inhibits the migration of grain boundaries in the uniform matrix will be insufficient to prevent the migration of the boundary between the larger grain and its smaller neighbors, and the large grain will consume its smaller neighbors. The rate of migration of this boundary is presumably proportional to the curvature of the individual curved sections. Since this is controlled almost entirely by the size of the small grains, the boundary should migrate at a uniform rate. Furthermore, the large grain will continue to grow until the small grains are entirely consumed, and it contacts another large grain. Growth will then stop. The ultimate grain size will thus be controlled solely by the number of large grains that appear.

This argument does not explain the nature of the fluctuation that leads to the appearance of the initial large grains. It could result from the local disappearance of a few inclusions, as the authors suggest, which would permit the local appearance of a very coarse grain. Any other cause for producing a large grain should lead to the same final sequence of events.

P. A. BECK—Dr. Burke gave a clearly formulated picture of the conditions of preferential growth of a large grain in a fine grained matrix (Jeffries' grain size contrast effect) in terms of the Harker-Parker mechanism. This picture is entirely in accord with our own thoughts on the subject, provided the fine grained matrix has no preferred orientation. When this preferred orientation is not

negligible, however, the picture needs to be supplemented by a mechanism which provides the strong dependence of the rate of growth of the large grain on its relative orientation with respect to its neighbors, as stated above. The exact nature of that mechanism is not yet completely clear.

Statistical Rate Theory of Metals—I. Mechanism of Flow and Application to Tensile Properties

By JAY W. FREDRICKSON and HENRY EYRING

DISCUSSION

(G. Gensamer and W. R. Hibbard Jr., presiding)

G. WENSCH*—The authors have

further advanced the basic fundamentals in the science of rheology. Upon the teachings of Bingham, Scott Blair, Houwink, and others we are approaching the solution of the inelastic behavior of metals.

In consideration of Fig 10, as the authors point out, the stress-strain curve follows line *MF* even after interruptions provided that relaxation effects do not occur. However if relaxation effects do occur, such that the behavior of the metal is inconsistent with the concept of an

* International Nickel Co. Graduate Fellow in Metallurgical Engineering, University of Illinois.

FIG 24—Analysis of Dushman's data after Ref. 43.

equation of state, transient phenomena will appear as clearly shown by the work of Carreker, Leschen and Lubahn.⁴²

W. C. ELLIS*—The authors in this paper have advanced a theory for plastic flow in metals which involves the translation of relatively small flow units or domains into existing holes made up of a number of adjacent unoccupied lattice sites. From the mathematical analysis of the stress-strain curves for a number of steels they have calculated an average value for the hole involved in flow. A range of values was found which group around about 200\AA^3 at room temperature. This volume corresponds to about 8 unit lattice cells which is a large hole in an atomic universe but a small one in relation to available measuring tools such as the electron microscope.

The mathematical analysis, by itself, seems to be merely suggestive and constitutes no proof of the physical existence of such holes, and it should be added that the authors do not contend that it does. Explicit evidence for the existence of such holes, if they be a reality, would be welcome for it would provide a firm foundation for a mechanism of plastic

flow, a foundation which does not exist, in my opinion, for any of the present theories. I would therefore like to ask if there is a method, or prospect of developing methods, of arriving explicitly at the physical reality of such holes in metallic structure. This paper is a valuable one in that it presents a new concept and it is hoped that investigation along this line will be continued.

C. ZENER* and T. S. KË*—The authors conclude that the heat of activation ΔH^* for the elementary act of plastic flow is essentially zero, and hence, that the free energy of activation ΔF^* is entirely an entropy effect. This conclusion, if correct, must form the starting point for any further development of the theory of plastic deformation. It is of utmost importance that their underlying assumptions be carefully scrutinized to see if this conclusion of a zero ΔH^* could possibly arise simply as a consequence of an artificial assumption.

The authors assume that the rate of an elementary flow process depends upon the applied stress S in the manner:

rate $\sim e^{-(\Delta F^*/kT)} \{e^{(VS/kT)} - e^{-(VS/kT)}\}$, [42] where the free energy of activation ΔF^*

and the volume V may depend upon the temperature but not upon the applied stress. Now one of the most characteristic features of crystalline plasticity, as opposed to amorphous plasticity, is the relative insensitivity of the flow stress S to changes in temperature. Thus by passing from room temperature to 1°K the flow stress corresponding to a given strain rate is increased by, at most, a factor of five. The assumption (Eq 42) is compatible with this characteristic fracture of crystalline plasticity only if both the ratios V/T and $\Delta F^*/T$ are relatively insensitive to changes in temperature. A zero heat of activation ΔH^* then follows from the constancy of the ratio $\Delta F^*/T$. The conclusion of the authors that the free energy of activation is essentially an entropy effect is, therefore, a direct consequence of the assumption (Eq 42).

In writing Eq 42 one implicitly assumes that the heat of activation Q of an elementary flow process is a linear function of the applied stress S . One of the writers (C. Z.)⁴³ has, in collaboration with J. H. Hollomon, shown that the extensive creep data of Dushman, Dunbar and Huthstein¹⁸ may most readily be interpreted through a relaxation of this assumption, that is, by regarding the heat of activation as a function $Q(S)$, the precise form of which is to be determined by experiment. Thus, in place of Eq 42 one has

$$\text{rate} \sim (e^{-Q(S)/kT} - e^{-Q-(S)/kT}). \quad [43]$$

The example of $Q(S)$ for pure aluminum is presented as Fig 24. Fisher and MacGregor,²⁸ whose data have been analyzed by Fredrickson and Eyring according to Eq 42, showed that their own data were consistent with Eq 43.

The present writers wish to ask Messrs. Fredrickson and Eyring if their physical picture of plastic flow necessarily demands a rate dependence containing the applied stress to the first power in the exponent, as in Eq 42, and whether a relaxation of this condition of an exponent linear in stress would not drastically modify their conclusions. They further wish to point out to Messrs. Fredrickson and Eyring that creep data at very low stress levels is not in agreement with the conclusion of a zero heat of activation. Such data have been analyzed by Kanter⁴⁴ who found that at those low stress levels where the creep rate is proportional to the stress itself, the creep rates for iron and for brass have heats of activation comparable to those for self diffusion.

J. W. FREDRICKSON and H. EYRING (authors' reply)—The authors wish to extend their appreciation for the interest shown in this paper.

The transient phenomena mentioned by Mr. Wensch has been observed⁴⁵ by the senior author in a subsequent investigation. A continuation of these transient investigations promises to enlighten us further on the flow mechanism.

* Bell Telephone Laboratories.

⁴² References are at end of discussion.

* University of Chicago.

The question proposed by Mr. Ellis regarding the physical reality of "flow holes" in a metallic structure is a very intriguing problem and deserves serious consideration. As is emphasized by Mr. Ellis, the authors have not established the physical existence of such holes. It does seem to be a reasonable assumption however, that in order for flow to occur by the movement of domains these domains must be provided with a space to occupy in their new positions. A mechanism for flow has been explained by some theories through the operation of dislocations. It is not our wish to enter into a discussion at present as to the difference between a "dislocation," "imperfection" or "hole." It suffices to say that some medium is apparently required to explain flow and the medium of holes has been used in this paper to provide the mechanism for flow. If one assumes that the size of the domain that moves is an inverse function of the applied stress, as appears to be the case, then the mechanism of flow could also occur by the creation of holes or new "home sites" by the domain itself as it moves.

At present there is apparently no method of determining explicitly the physical existence of holes in metallic structures. As Mr. Ellis suggests, the development of such a method would contribute greatly to the knowledge of flow in metals. It is the authors' belief that such a determination can be secured by the methods of statistical mechanics and further work is being directed toward this end.

Messrs. Zener and Kê have presented a very interesting and thoughtful discussion. The points introduced in this discussion are well taken and merit consideration not only by the authors but by others interested in flow mechanisms.

The rate equation for the elementary flow process shown as Eq 42 in the discussion was developed after careful consideration of various flow processes occurring in solid materials including that of viscous flow. The fact that the apparent heat of activation ΔH^* for flow was essentially zero, and thus the free energy of activation ΔF^* was entirely an apparent entropy effect, was a direct consequence of the application of the elementary rate equations to metallic deformation. That this result might possibly have occurred by the use of some other assumption can not be categorically denied. But first, let us examine the equation a little more closely.

If in Eq 42 $VS \gg kT$ we have

$$\text{rate} \sim e^{-\frac{\Delta F^*}{RT}} e^{\frac{VS}{kT}} \quad [44]$$

and the equation gives the same type of exponential dependence of rate on stress that is found empirically. On the other hand if $VS \ll kT$, one has approximate proportionality of the rate to the stress as in viscous liquids and as shown by Maxwell.³³

FIG 25—(a) (above) Curves showing $\Delta F^*/T$ vs. temperature relationship. (b) (below) Curves showing V_h/T vs. temperature relationship.

If one rewrites Eq 44 in the form

$$\ln \text{rate} \sim -\frac{\Delta F^*}{RT} + S \frac{V}{kT} \quad [45]$$

the stress is shown as a function of the logarithm of the rate. Eq 45 is clearly seen to fit the curves of Fig 24.⁴³

A further analysis of the data in the paper shows that $\Delta F^*/T$ and V_h/T are relatively insensitive to changes in temperature, as was deduced by Messrs. Zener and Kê. Fig 25, representing Fig 2 and 3 from this analysis, shows the relationship of $\Delta F^*/T$ and V_h/T as a function of T .⁴⁶

It has been determined by the senior author in a separate subsequent investigation of creep⁴⁶ that both the free energy

of activation ΔF^* and the hole volume V_h are inversely dependent upon the applied stress. Because of this stress dependency, one must be careful in making an analysis that the underlying mechanism does not change within the stress range.

One may well consider that the mechanism of flow occurs by the process of self-diffusion in that at equilibrium the energy barriers that must be crossed are sufficiently high to prevent flow, or conversely, the probability for flow in any one direction is as likely as in any other and therefore flow will not occur without a directed driving force. The action of the applied stress is to provide the driving force for flow by raising and lowering the

equilibrium positions on each side of the energy barrier as depicted by Fig 2. Thus, if the barriers are lowered in a preferred direction by some means, flow can occur by self-diffusion of domains across the barrier.

Messrs. Zener and K₂ have proposed a rate equation as shown by Eq 43. It appears that in order for this equation to fit the curves shown in Fig 24 the parameter Q must be some linear function of stress. If Q is some linear function of the stress, then Eq 42 and 43 differ only in the definitions of the exponents. Deter-

mining which equation is the more correct will require further investigation. It is the belief of the authors that the amount of data so far analyzed has been too meager to be used as a definite criterion to determine the nature of the parameters in the equation. In any event it is gratifying that separate investigations do produce such qualitative agreement.

JOINT DISCUSSION

(G. Gensamer and W. R. Hibbard, Jr., presiding)

G. WENSCH*—Messrs. Carreker, Leschen and Lubahn are to be congratulated on their excellent paper "Transient Plastic Deformation." As the authors correctly point out little thought has been given to transient phenomena in metallurgical experimentation; however, considerable effort has been made to analyze the rheological behavior of solids by mathematical treatment.

By the proper combination of visco-elastic models such as the Maxwell and Kelvin bodies one can imitate many of the observed behaviors in metals, such as the elastic after-effect, yield point and the transient behavior.^{7,8}

With a slight modification of the visco-elastic model system given by Burgers⁹ one can obtain a generalized strain-time curve similar to that of Fig 2 in the above-mentioned paper. By the proper evaluation of the constants of viscosity and elasticity the two curves would probably be unique. The writer submits a sketch of a visco-elastic model which would exhibit generalized transient behavior, see Fig 9.

The solution of the differential equation of the model is:

$$1. x = \phi_1 \int_0^t P dt + \phi_2 \int_0^t P(t_1) e^{-(t-t_1)\phi_2/\alpha_2} dt$$

$$2. \text{ when } P = P_1, 0 < t < t_1$$

$$x = \phi_1 t P_1 + \alpha_2 P_1 (1 - e^{-t/\alpha_2})$$

$$\mu = \frac{\alpha_2}{\phi_2}, P_1 > P_2$$

$$3. \text{ when } P = P_2, t_1 < t < t_2$$

FIG 9—Rheological model which demonstrates transient behavior.

$$x = \phi_1 P_2 (t - t_1) + \alpha_2 P_2 (1 - e^{-\frac{t-t_1}{\alpha_2}}) + \phi_1 P_1 t_1 + \alpha_2 P_1 (1 - e^{-\frac{t_1}{\alpha_2}})$$

By proper evaluation of the constants ϕ_1 , ϕ_2 and α_2 , the strain x may be plotted versus the time t to give a curve similar to the upper curve of Fig 2 in paper discussed. (Fig 10).

Perhaps the authors can be induced to comment on visco-elastic model analysis as a means of interpreting transient behavior.

It appears that the authors did not

account for the change in the cross-sectional area of the wire which occurred during their investigation. Did the authors find this area reduction to be negligible?

J. G. LESCHEN (authors' reply)—With a suitable combination of springs and dash-pots one can undoubtedly reproduce many experimental results. The authors prefer not to depend too much on this sort of model since they feel that in many cases it does not represent adequately any real mechanism in the metal. However, this type of model is frequently of considerable value.

In the initial experiments no account was taken of the change in cross-sectional areas of the wires, since the reduction was negligible. In the experiments with which the sigmoidal curve was determined, the stress was automatically maintained constant by the device described by Fisher and Carreker.¹⁰

R. MADDIN* and W. R. HIBBARD, JR.*—The very interesting study of the dynamics of slip bands is a welcome addition towards the general solution of the problem of plastic deformation of metallic single crystals. There are two points which should be considered in light of recent experiments conducted at Hammond Laboratory.

In conjunction with Professor Henry A Lepper, Jr. (Department of Civil Engineering, Yale University), a single crystal of alpha brass 37 mm in diam was slit into 6 square crystals 180 mm long by 3.6, 4, 5.2, 7, 7.9 and 13 mm on the edge, respectively. Each crystal was etched to remove cold-work, homogenized for 20 hr at 800°C, polished electrolytically and X rayed via the back reflection method to insure that the machining operation left

7,8 References are at the end of discussion.

the orientation unchanged. An SR-4 strain gauge, type A-1, was glued on each specimen and the crystals were stressed to just beyond the yield point. The slip lines were counted on four of the specimens (too much glue on the remaining two specimens obscured the lines). The largest specimen showed a total of 70 lines observable at a magnification of 600 diam along a 150 mm gauge length whereas the smallest crystal showed over 8000 lines observable at $600\times$ for a 25 mm (only $\frac{1}{8}$ of gauge length). The number of lines on the other crystals was intermediate between those for the two extreme sizes and decreased with increasing size of the specimen. These preliminary results of this investigation, which is still in progress, have thus far produced experimental evidence which is not in accord with the statements made by the authors on p. 3 of their paper, "Nucleation of Slip Bands."

In the investigation of Ono quoted by the authors, two variables existed, namely, specimen diameter and orientation. Recent work being conducted at Hammond indicates that alpha brass single crystals of the same diameter pulled in tension under similar conditions but with differing orientations, when referred in the usual manner to the principal [111] plane in the principal $\langle 110 \rangle$ direction, give values for critical resolved shear stress too widely separated to be accounted for by experimental inaccuracies. Thus, variations in crystal orientations might account for Ono's differing critical resolved shear stress values. Furthermore, the curves redrawn from Ono in Fig 3 represent resolved shear stresses at shear equal to 4×10^{-5} and shear equal to 100×10^{-5} rather than a true critical resolved shear stress. The curve representing the resolved shear stress at shear equal to 0 (that is, the critical resolved shear stress) does not show so marked a downward trend and the data points deviate from the drawn curve making them difficult to generalize. It is also possible that the downward trend in Ono's curves and those redrawn in Fig 3 of the current paper might conceivably be rationalized on the basis of a variation of rate of strain hardening as a function of specimen diameter.

J. G. LESCHEN—We now realize our error in including in the present paper the curves from Ono and admit that they should be interpreted with caution.

However, a size effect is still to be expected. It should be a more complicated one than the present paper indicates, since the displacement per slip band δ and the number of slip bands N per unit length of specimen should also be considered. For example, if one assumes that the formation of a slip band in a specimen of diameter D relieves all the elastic energy stored in an approximate volume D^3 , δ should vary as the product τD where τ is the stress at which

FIG 10—Schematic strain-time curve.

the slip band started. The observed strain would then vary as $N\tau D$.

Now as I understand these experiments with brass crystals, the specimens were pulled to a constant strain and then the number of slip bands counted. Is that correct?

R. MADDIN—Relatively.

J. G. LESCHEN—Constant strain requires the product $N\tau D$ to be approximately constant. This requirement is consistent with the observations of Messrs. Maddin and Hibbard that N decreases with increasing D . It is difficult to say how τ should vary under these circumstances, and a report of any such variation in these experiments would be very interesting. The situation is further complicated by the likelihood that all the slip bands did not start at the same stress.

L. D. JAFFE*—The theory outlined by the authors is obviously worthy of most careful consideration, especially in view of its successful prediction of certain transient effects. I should like, however, to confine my remarks to Fig 4 of the paper, "Nucleation of Slip Bands," and the text pertaining to this figure.

The authors explain the portion of the observed yield strength vs. $T^{-1/4}$ curve that represents a straight line through the origin (Fig 4) on the basis of the first exponential in Eq 3. They attribute the deviation at higher temperatures to the influence of the second exponential and to decrease in the modulus G . However, the second exponent differs from the first simply by a factor of 2. A brief calculation shows that even if the whole variation in yield strength with temperature were attributed to the second exponential, the slope would be increased by a factor of $2^{1/4}$, or only 19 pct. The observed increase, according to Fig 4, is obviously very much greater than this. Thus, the second exponential of Eq 3 is of little help in accounting for the change in slope. Do the authors, therefore, believe that the deviation observed is primarily due to decrease in the modulus?

* Watertown Arsenal Laboratory.

W. C. ELLIS*—Jay Fredrickson in our Laboratories has conducted creep tests similar to those for which Carreker, Leschen and Lubahn report the results in Fig 2 of their paper, "Transient Plastic Deformation." These tests were made on high purity lead with tensile specimens of rectangular cross-section, approximately 0.500×0.100 in. The strain rate curves as a function of time were similar to that shown in Fig 2 including the high rate of strain on initial application of stress decreasing slowly with time to a nearly constant rate. When the stress level was decreased the strain rate became zero for some time and then increased gradually to a nearly constant rate smaller than that for the initially higher stress. These are qualitatively the same transient effect as reported by the authors and would follow from the relationships developed in the companion paper, "Nucleation in Slip Bands."

The energy relationships which the experimental evidence qualitatively confirms were developed from the concept of nucleation in slip bands and the experimental findings are therefore qualitatively consistent with the nucleation concepts, as the authors have stated. There is a tendency when such an agreement is found between experimental data and a postulated mechanism to go further and to consider that the consistency observed points to a high probability for the physical reality of the mechanism.

There is a question, however, of whether a postulated mechanism, such as this, can be said to be unique from confirmation by property relationships alone, when such relationships might conceivably arise from other physical mechanisms. I would like, therefore, to ask Mr. Leschen to discuss this in more detail. How strongly do the experimental findings point to nucleation in slip bands as a part of the physical mechanism of flow in metals?

J. G. LESCHEN—Thank you, Dr. Ellis. I am glad to learn that someone else has performed this sort of experi-

* Bell Telephone Laboratories.

ment and obtained similar results.

I should like to emphasize that the present papers are not primarily concerned with the physical mechanism of slip. They simply seek to determine whether or not the nucleation concepts are applicable to the slip process. The results of the experiments indicate that slip bands do behave like anything else that is nucleated. Nucleation concepts should therefore be applicable to any mechanism of slip, whether that mechanism be described by dislocation theory or by the theory of Fredrickson and Eyring or by any other theory.

D. W. WHITE*—As I understand it, one corollary of this theory is that the small surface imperfections in the crystal would tend to facilitate the nucleation of the slip. On the other hand, Dr. McAdam showed us this morning that the low stress of a specimen on a larger scale is raised as you introduce the triaxial by means of a notch.

This seems on first appearance a little inconsistent with this matter of the function of surface imperfections by the nucleation theory. I was wondering if this is really a contradiction or just something imaginary on my part.

J. G. LESCHEN—The stress field in the vicinity of a notch is not as simple as that assumed in the present papers. It is difficult to say what the effect would be on the nucleation and growth of a slip band.

G. H. BOSS†—The authors of these two papers have outlined a very provocative theory and have presented the results of some very beautiful experiments. Their theory is certainly as tenable as are some of the others which attempt to explain slip. However, it is not necessary to postulate nuclei as the generators of slip in order to explain the curves which they have derived from the results of these excellent experiments.

While a metal is in the steady stage of creep it is being subjected to two opposing phenomena. One of these is the work hardening which occurs as the result of the deformation to which it is being subjected; the other is the recovery anneal, which occurs at a rate determined by the temperature to which the metal is heated.

In the following discussion it is assumed that the temperature is held constant, thereby fixing the rate of recovery annealing: If a metal is creeping at a steady rate caused by a load L , it will be work hardened to the extent determined by the balance between the rate of extension and the speed of recovery anneal. Now, if the load is increased by an amount ΔL , the balance is upset because the metal has only the work hardening of the lower load to resist the newer, greater load. Consequently the metal is deformed at a very great rate, which gradually diminishes as the work

hardening of the metal is increased. It finally reaches a steady rate which is somewhat higher than the original. Then if we reduce the load back to its original value of L the balance is again upset, because the metal is work hardened to the extent demanded by the higher load. Consequently the rate of extension is greatly reduced, and remains so until recovery has restored the balance by reducing the work hardening of the metal.

A. H. COTTRELL*—The idea that slip may be nucleated by the formation on a slip plane of a disc-like patch of slipped material which subsequently grows by the outward advancement of its boundary across the slip plane is much older than the authors suggest. It was proposed and discussed by Orowan¹⁴ in 1934. In reintroducing the idea, the authors suggest that it is in some way different from the dislocation theory; this is strange in view of the fact that Orowan and many others have emphasized that the boundary (which divides the slipped and unslipped parts of the slip plane) of the disc-like patch constituting the nucleus of slip is rigorously definable as a dislocation. This model of slip nucleation has been discussed, explicitly and implicitly, many times^{1,15,16,17,18,19,20} since 1934 and the general conclusion has now been reached that an extremely high energy of formation precludes the existence of slip nuclei as equilibrium features of a crystal under external stress, unless this stress approaches $G/10$ in order of magnitude, where G is the shear modulus. Accordingly, modern opinion holds that such nuclei exist only as metastable features in crystals, the dislocations which form their boundaries being trapped in potential energy troughs caused by the stress fields of impurities, crystal boundaries, and other dislocations. In the absence of these troughs, or of a very high shear stress on the glide planes, the nuclei must disappear.

The concept of a slip nucleus which the authors propose on p. 2 of "Nucleation of Slip Bands," as a basis for their theory is perplexing. It is founded on the assumption "that a growing semicircular interface, *across which no shear stress is supported*, advances slowly into the crystal." The clause in italics must mean that the material in the slip nucleus is incapable of supporting a shear stress, or that it happens to be free from stress at the time considered. From the work of Bragg,¹⁸ who has studied the second possibility in detail, one can conclude:

1. That it arises when the applied shear stress τ bears a certain relation to the amount of slip (which is fixed by the crystal structure) in the slip nucleus, a relation which also involves the size of the nucleus and the elastic properties of the medium,

2. That, when its consequences are

fully analyzed, it reduces the above model of slip to a particular case of the dislocation theory model, in which the stress fields from the applied load and the dislocation constituting the boundary of a slip nucleus approximately cancel each other inside that nucleus.

The authors evidently have in mind the first possibility (that is, that the slipped region cannot support a shear stress), since:

1. No suggestion is made of any critical relation between the applied stress and the amount of slip; in fact the amount of slip is not mentioned at all.

2. The energy of nucleation is taken to be made up of a term representing relief of shear stress in the vicinity of the nucleus and a surface energy term proportional to the area of the slipped region.

To suppose that the slipped region cannot support a shear stress must mean either that the material in the disc-like patch has become a fluid (see below) or that the two atomic planes which have slipped over each other in this region have parted company, thus forming a crack. The authors presumably favor the latter since they compare the disc-like patch to a slit.

What is now very difficult to understand is how this model can describe the process of plastic gliding since the picture it gives is of the spreading of a crack across a slip plane, which is something quite different. If the material within the slipped region cannot support a shear stress, then, when the "slip" has propagated across the entire slip plane, the two halves of the crystal divided by the slip plane must become separated. Brittle failure along a slip plane, and not plastic flow, should result.

The conclusion seems unavoidable that no other model of a slip nucleus is conceivable except the strict dislocation model in which the atoms in the slipped region have slipped past each other to congruent positions where they are as firmly bound and are as capable of supporting a shear stress as those in the unslipped region. Only the dislocation itself, where a special atomic configuration exists, is incapable of supporting a shear stress, and this only in the sense that the dislocation will move in that direction which causes the crystal as a whole to give way to the stress.

The fact that a crystal as a whole cannot support a shear stress without undergoing plastic flow, if it contains dislocations, raises the possibility that the authors may regard their slip nucleus as a macroscopic, disc-like piece of crystal containing many slip nuclei of the strict dislocation type. This is an alternative to the crack interpretation and could be regarded as a refinement of the concept of the slipped region as a "fluid." In such a case the energy required to form the macroscopic slip nucleus would be the sum of the self energies and interaction

* University of Birmingham, England.

energies of all the nuclei (of the dislocation type) from which it is made up. We shall now show that the energy of formation is impossibly high for even a single slip nucleus of the dislocation type. Consider the formation of a circular patch of slip in the interior of a crystal, constituting a single slip nucleus of the dislocation type. (The slightly more complicated case of slip starting from the surface can also be treated by making use of Koehler's¹⁷ surface image force.) The critical radius determining whether the nucleus will grow or disappear under a given stress is found by equating the forces acting on the dislocation forming the boundary of the nucleus. Three forces act:

1. An outward force, causing the dislocation to spread, which is due to the applied stress. This force increases as the nucleus grows.
2. An inward force due to the attraction towards each other of the parts of the dislocation on opposite sides of the nucleus. This force decreases as the nucleus grows.
3. An inward force due to the fact that, as the nucleus grows, the length of the dislocation round its boundary increases and so the amount of highly strained material in the core of the dislocation increases. It can be shown^{17,18} that the strain energy of the material in the core of a dislocation is generally smaller than the interaction energy of the strain fields which causes force (2), so that, in a rough calculation, force (3) can be neglected in comparison with force (2).

A balance between forces (1) and (2) is obtained approximately when the stress fields acting on any part of the dislocation due to the applied stress and the dislocation on the other side of the nucleus are equal. This defines the critical radius of the nucleus roughly as $\gamma = G\lambda/2\pi\tau$ where G and τ have their previous meanings and λ is the slip distance ($\sim 3\text{\AA}$). The energy of such a nucleus could be computed accurately, but for a rough estimate we can note that the energy of a dislocation is, at least, $1eV$ per atom along its length.²⁰ Hence under a stress τ , the energy of nucleus formation is about $2\pi\tau/\lambda = G/\tau$ eV. Strictly, one should subtract from this the work done by the external forces, but, unless these are such that $\tau > G/100$, the inclusion of this work does not affect the order of magnitude of the result.¹⁹ For soft metals G is of the order of 1000τ , so that an energy of about 1000 eV is required for slip nucleation. With a Boltzmann factor of $e^{-40,000}$ operating, there can be no possibility of stable slip nuclei at the elastic limits of soft metals. Only under exceedingly high stresses ($\sim G/10$) could the possibility be admitted. While the above estimate is undoubtedly rough, it ought to be correct in order of magnitude. More exact treatments have been developed^{17,18,19} for nuclei bounded by straight

dislocations, which give essentially the same results.

The experiments on transient plastic deformation⁷ cannot be regarded as providing evidence uniquely supporting the slip nucleation theory since Orowan²¹ has shown that the same effects are to be expected on the recovery theory of creep. Indeed, the times of the induction periods noted (~ 10 min. for lead and > 5 hr for copper) seem more in accord with a recovery theory than the theory of slip nucleation.

A. H. SULLY*—Although the paper, "Transient Plastic Deformation," makes no reference to the fact, it may be presumed that the wires on which these tests were carried out were polycrystalline aggregates and not single crystals. In this case, it seems more than probable that the results obtained in the tests, involving a reduction of stress during creep, are complicated by normal creep recovery effects. Creep recovery always accompanies stress reduction in polycrystalline aggregates, due to the redistribution of elastic stress between differently orientated crystals, which have different values of the resolved shear stress along the slip plane, and, consequently, have varying degrees of elastic and plastic distortion. In the case shown in Fig 2, where a small reduction of stress results in an apparently constant strain for a short period before creep recommences, it seems possible that this could be due to a balance between recovery processes in some crystals and continuing creep in others. If this were true, an actual diminution of strain would be expected to occur if the stress reduction was larger, and it is unfortunate that the authors do not give the results of experiments with larger reductions of stress, since this would be a more critical test of their theory. The statement in the introductory paragraphs that transient effects have not previously been recognized in experimental work is incorrect. Tapsell²² has published data illustrating creep recovery and in particular has shown for a 3 pct nickel steel at 400°C the effect on the creep of reducing the stress from 16 tsi to 14 tsi. This shows, after allowing for the elastic strain, strain first diminishing, due to recovery effects, and then increasing and gradually approaching a new steady state creep rate.

The shape of the curve shown in Fig 3 from one minute onwards, relating the length of the period of zero strain rate to the time of prior application of the higher stress, can similarly be accounted for on existing theory if Andrade's division of creep into transient and quasi-viscous components is accepted and it is taken that only transient creep is recoverable in polycrystalline aggregates. There is adequate evidence that this is the case, for example, Chalmers²³ on the creep of

tin. After the time of exhaustion of primary creep, the recovery accompanying a constant stress reduction therefore remains the same, irrespective of the period for which the higher stress is applied, in accordance with the authors' observed approach to constancy of their "incubation" period. The rapid increase in creep rate and subsequent decrease to a constant rate observed on increasing the stress can similarly be explained on the basis of existing theory by Orowan's²¹ concept of an activation energy for glide increasing with the creep deformation along a curve similar to the normal stress-strain curve. An increment in the stress therefore results in a sudden lowering of the activation energy for further slip and consequently a further stage of transient creep, the exhaustion of which corresponds with the achievement of a constant creep rate, observed by the authors. It may be suggested, therefore, that the authors' results can be satisfactorily explained on the basis of existing knowledge of transient creep, and of the deformation of polycrystalline aggregates, and the evidence in favor of the theory of Leschen, Carreker, and Holloman would only be convincing if they observed identical effects, especially those accompanying stress reduction, in single metallic crystals.

J. G. LESCHEN—The authors regret that a misunderstanding has arisen with Professor Cottrell through their apparent failure to make sufficiently clear certain points in their introduction. They did not mean to imply that the idea of an advancing boundary of slip was at all new or that the dislocation and nucleation concepts are incompatible with one another. The authors merely wished to suggest that since nucleation theory can be successfully applied to the growth of cracks and of particles of a second phase, it might likewise be applicable to the growth of slip bands. In order to determine if it were so applicable, they selected a simple model—undoubtedly an oversimplified one—and then qualitatively investigated the characteristics of that model. Since these characteristics proved to be in reasonably good agreement with experiment, as reported both in the present papers and in a later development by Hollomon,²⁴ a nucleation theory of slip seems to merit further attention and a more quantitative development.

The present rudimentary treatment did not seem to warrant any undue concern with the atomistic mechanism by which slip takes place. In future developments of the theory the mechanism will have to be taken into account, and there can be little doubt that dislocations will here play a large part. In this regard the comments of Professor Cottrell should be of great help. The authors take issue with several of his remarks but feel that a discussion of most of them belongs more properly in a future note or paper

* Fulmer Research Institute, England.

FIG 11—Transient effects in creep test on single crystal of lead.

than in the present discussion. However, several points can be made. For example, in calculating the Boltzmann factor for nucleating a dislocation, Professor Cottrell neglects the fact that yielding may begin at places where the local stress is significantly higher than the average applied stress. At such places, as Cottrell points out, the work done by the external forces cannot be neglected. Furthermore, we wonder whether the value of 1 eV , taken from the calculations of Nabarro, is a total energy or is it the free energy that must be used in computing the Boltzmann probability.

Mr. Sully is quite correct in presuming that the wires used in the original experiments were polycrystalline. However, tests have since been carried out with single crystals, and the results of the few experiments thus far completed indicate that the behavior of single crystals is essentially the same as that of polycrys-

talline specimens. Fig 11* illustrates, for instance, the response of a lead specimen to changes of stress at room temperature. Etching and visual examination of this particular specimen before the creep test indicated that it was a single crystal. X ray diffraction photographs made several days after the test showed the specimen to possess some lineage structure and a few small grains (possibly from local recrystallization). The suggestion that experiments be made with larger reductions of stress is a very valuable one and the authors have undertaken such tests.

Although the paper by Tapsell is not at present available to the authors, the

*The strain rate-time curve was obtained by graphically determining the slope of the strain-time curve, except in the region following the decrease of stress. Here the strain-time curve was so flat that accurate measurements of the slope could not easily be made, and the method of differences was therefore used. This method yielded points with appreciable scatter, and it accordingly seemed appropriate to show them in Fig 11.

type of results which he observes, as reported by Mr. Sully, is familiar.²⁵ However, this sort of transient does not appear to be the same as that discussed in the present papers, since the authors observed no contraction other than an immediate elastic one upon reduction of the stress. The transients of Tapsell probably require more complicated explanations of the kinds summarized by Leschen²⁶ and Zener.²⁷

In reply to Dr. Jaffe, it does indeed appear that the decrease of modulus with increase of temperature is primarily responsible for the deviation of the yield strength versus $T^{-1/2}$ curve from a straight line. The work of Kê²⁸ indicates that the decrease in modulus of single crystals is appreciable; and there is reason to believe²⁹ that as the melting point is approached the modulus, of polycrystals at least, falls toward zero.

Messrs. Cottrell, Sully, and Boss point out that the observed transient effects can be explained equally well by the creep recovery theory of Orowan. An experiment which would differentiate between this and the nucleation theory is difficult to conceive. A choice between the two will perhaps depend upon which can be the more adequately developed.

The nucleation theory of slip will no doubt require considerable modification. Meanwhile, it should serve to direct attention to the type of experiment involving sudden changes of stress, strain rate, or temperature. Then, if the theory should ultimately prove to be untenable, it will at least have been of heuristic value.

Plastic Deformation of Large Grained Copper Specimens

By W. R. HIBBARD, JR., Junior Member AIME

DISCUSSION

(R. F. Mehl and J. C. McDonald
presiding)

R. F. MEHL*—It is certainly pleasant to have a paper in the field of the plasticity of metal crystals that modestly undertakes to study some of the complexities from a phenomenological point of view, advancing new and good information and employing theory with judgment and restraint. In the long view, progress ought to come from a nicely calculated mixture of theory and experiment; and the proportions of each in that mixture should be chosen with some regard for the stage of development and the degree of complexity involved. Despite the great attention that has recently been given to physical theory in the field of metal behavior generally—the many symposia, the innumerable papers, the approval that is accorded semi-religiously to any effort so long as dislocations or lattice vacancies are intoned—it seems clear to this observer that progress in understanding plasticity has been shockingly slight. A proper sense of responsi-

bility should be shown in a field of research; theory should not far outrun experiment, for even though there is good sport in this, the purpose is not one of entertainment. Nor should undirected experiment be the rule; but at the present the error is not in this. There is a need of systematic experimentation in this field, and from this a formulation of general modes of behavior, for which then we might hope to have theories of behavior, and not before. The metallurgical profession ought to remember this, as Dr. Hibbard evidently does, and as some physicists do not.

As to the problem at hand, the plasticity of aggregates, it is possible that some of the difficulties arise in a lack of knowledge of the conditions of flow under various circumstances of restraint. We have based our thinking on the Polanyi-Schmid principle of a critical resolved shear stress for slip, providing slip on that lattice plane and in that direction for which the resolved shear stress is a maximum; it is possible that if this principle is not general, we could profitably restudy aggregates. Dr. R. Smoluchowski

in the Carnegie Metals Laboratories has recently demonstrated that slip in single crystals of aluminum in the form of thin plates does not conform to the Polanyi-Schmid principle, but that the length of the slip direction through the piece itself is a determinant—that slip is the reader the shorter this direction, that slip may occur in a given plane in a given direction when the length of the slip direction is short even though this slip system does not exhibit the maximum resolved shear stress. This effect of external geometry is in the category of restraint; it would be very interesting to see whether the change in basic thinking which this experiment implies might alter our conceptions of how aggregates should behave.

W. R. HIBBARD, JR. (author's reply)—I should like to thank Dr. Mehl for his kind remarks. His philosophy of scientific progress is a very important guide to investigations and, unlike the chicken or egg story, gives us a lead to the answer of which should come first, theory or experimental fact.

Dr. Smoluchowski's findings are extremely interesting and important. We now have another variable to consider in deformation studies.

Plastic Flow in Anisotropic Sheet Steel

By L. R. JACKSON, Member AIME, K. F. SMITH and W. T. LANKFORD

DISCUSSION

(R. F. Mehl and J. C. McDonald
presiding)

R. HILL*—Apart from notation, the anisotropic stress-strain relations used by the authors are equivalent, in the special case when the directions of principal

stress and orthotropy coincide, to those which I have derived by other methods in an earlier paper.⁷ The criterion of yielding which I proposed is also similar in form to the authors' expression $\bar{\sigma}$, although I cannot make out whether they

⁷ A Theory of the Yielding and Plastic Flow of Anisotropic Metals. *Proc. Roy. Soc.*, (1948) 193-A, 281.

actually identify $\bar{\sigma}$ with the function governing yielding. It seems that they do not, since in the second paragraph of their summary and conclusions they state that their method is consistent with the idea that "the flow is governed primarily by considerations of shear-strain energy."

The value of the paper would have been greatly enhanced if detailed data had been given concerning the observed strain-ratios in the bulge tests. These can

* Cavendish Laboratory, Cambridge, England.

be predicted theoretically from the stress-strain relations in terms of the measured strain-ratios in the tension tests at right-angles. An immediate test of the validity of the stress-strain relations is then possible. Would the authors be good enough to give these data? I should also be very interested to check the relations given in my paper between the yield stresses in the orthotropic directions and the parameters occurring in the stress-strain relations.

I have found it very difficult to make out what fundamental postulates the authors are making with regard to the influence of cold work on the values of the anisotropic parameters. They appear to assume tacitly that these parameters increase in strict proportion. This seems rather unlikely on general grounds, but if it is true it certainly makes the problem of plastic anisotropy considerably easier. (In my own paper I left open the question of the dependence of the anisotropic parameter on the strain-history.) The second postulate made by the authors appears to be that the effective stress $\bar{\sigma}$ is a function only of the total plastic work. This is the natural assumption to make by analogy with the isotropic theory. However, could it not have been tested more directly by comparing the results of the two tension tests at right-angles? Would the authors please give the relevant data for this comparison?

The agreement between the bulge and tensile tests is, on the face of it, very satisfactory, but here again the authors have withheld the data that would enable a reader to assess whether the agreement is significant.

R. F. MEHL*—I would like to ask Mr. Jackson what are his ideas concerning the departure of Cor-Ten in behavior from his calculations.

L. R. JACKSON (authors' reply)—We have no concrete ideas as to just why Cor-Ten behaved as it did; however, throughout the analysis we made assumptions which may not have been justified in the case of Cor-Ten. Three such assumptions are: 1. That the flow curves in tension and compression are identical. 2. That the materials being investigated were orthotropic and that the orthotropic axes could be identified with the length, width, and thickness directions in the sheet. 3. That differences in the rate of straining in the bulge and tension tests had a negligible effect on the shape of the flow curves. 4. That the bulge test applies stresses only along the orthotropic axes. This last assumption is not correct and is particularly evident for circular bulges where there is no real choice of axes. 5. We also believe that the methods of measuring the parameters K_{xx} and K_{yy} are crude and not particularly precise.

R. F. MEHL—Do you think it possible that your results might be affected by

variations in the ductility properties in the thickness direction?

L. R. JACKSON—We attempted to minimize the effect of nonuniform thickness by measuring the thickness of test pieces at numerous locations and selecting only those which were uniform within narrow limits.

R. F. MEHL—It is disturbing that we have hitherto been forced to consider plastic properties, even when the behavior in the transverse direction is important, on the assumption that the ductility in the transverse direction (the thickness direction in plate or sheet) shows no special characteristics. Recent studies at Carnegie on the transverse mechanical properties of heat-treated forging steels show that the transverse ductility properties vary greatly from the longitudinal; and though this doubtless originates in the structural anisotropy caused by alloy segregation and its consequences in heat-treatment, it is possible that a similar mechanical anisotropy, perhaps less in degree, may occur in simpler alloys; there is no information on this point, and it should be developed. The effect might well be present in Cor-Ten, which the author studies, for this is an alloy steel, and should show a degree—not necessarily a harmful one—of alloy segregation and resultant mechanical anisotropy.

M. F. SAYRE*—Was any measure-

* Union College.

ment made on stresses in the 45° direction? From the theoretical point of view, evidence of anisotropy should be much more evident with measurements at 45° than with measurements taken 90° apart.

L. F. JACKSON—We did not measure the tensile properties in directions other than the rolling direction and the width direction; however, we are making these tests now.

MEMBER—How did you calculate the stresses in the elliptical bulge?

L. F. JACKSON—We had some difficulty in this measurement. We did not believe that the conventional method of computing stresses by assuming that the ellipse is a figure of revolution was precise enough, so the method had the following steps: 1. A bulge was blown to some selected height and the pressure released. 2. Either Tuckerman or wire strain gauges were mounted at the top of the bulge along the rolling direction and width direction. 3. The oil pressure under the bulge was then gradually increased to the value it had when the pressure was released. Simultaneous strain and pressure readings were taken during this period and a relation between the two strains and the pressure was obtained. The stresses existing at the maximum pressure were then computed from the strains by conventional methods.

MEMBER—How constant did that ratio remain during your test?

L. F. JACKSON—Do you mean the ratio between the stresses in the longi-

tudinal and transverse directions?

MEMBER—Yes.

L. F. JACKSON—The ratio remained quite constant for any one test; however, the ratio obtained depended on the kind of steel.

The authors regret that Dr. Hill's excellent paper was not available at the time theirs was submitted and are glad to have the opportunity afforded by his discussion to acknowledge it.

With regard to his suggestions we have the following comments.

Within the precision of our measure-

ments which was not high, the anisotropy parameters do not vary with cold work within the range covered. We wish to point out, however, that we did not explore the region in the vicinity of the yield point in detail because the assumption of incompressibility is not valid there. The parameters appeared to be essentially constant even after necking started when measured at the minimum section of the neck.

We are inserting Table 3 giving the data on the bulge tests requested by Dr. Hill. In the table we are also giving the

radii of curvature at the top of the bulge, since this data would be required in order to take into account the fact that the bulge tests do not apply stresses only along the orthotropic axes. This should be taken into account in attempting to compute the strain ratios as Dr. Hill suggests. As noted in the paper, we did not take this factor into account in computing $\bar{\sigma}$.

The tension data for the two directions can be computed from the tension curves given in the figures through the use of Eq 21 and 22.

The Effect of Thermal-mechanical History on the Strain Hardening of Metals

By J. E. DORN, Member AIME, A. GOLDBERG and T. E. TIETZ

DISCUSSION

(R. F. Mehl and J. C. McDonald
presiding)

G. W. GEIL* and N. L. CARWILE*—Tests of a type similar to those reported in this paper were carried out recently by the writers at the National Bureau of Standards with ingot iron. Complete true stress-true strain curves, up to the point representing fracture, were obtained for specimens prestrained at one temperature and extended to fracture at a different temperature. The curves were derived from simultaneous load and diameter measurements made during the tension tests. The results are in agreement with those reported in this paper in that they do not conform to the assumptions proposed for a mechanical equation of state. Tension tests made previously with an ingot iron, an 0.12 pct carbon steel and an 0.46 pct carbon steel, in which the specimens were prestrained various amounts at room temperature and then extended to fracture at 85°K gave similar results. These results were discussed in a paper on the "Influence of Plastic Deformation, Combined Stresses and Low Temperature on the Breaking Stress of Ferritic Steels" by D. J. McAdam, Jr., G. W. Geil and R. W. Mebs, published in *Metals Technology*, Aug. 1947.

The results of tension tests made at room and at low temperatures on commercially pure aluminum (99.4 pct) and high purity aluminum (99.97 pct) were discussed in a paper on the "Effect of Combined Stresses and Low Temperatures on the Mechanical Properties of Some Non-ferrous Metals" by D. J. McAdam, Jr., G. W. Geil, and R. W. Mebs published in the *Transactions of the American Society for Metals*, (1946)

37. The true stress-strain curve for aluminum extended at 85°K, warmed to room temperature, and subsequently extended further at 85°K, was not a continuous curve. The warming of the metal to room temperature resulted in some softening or crystal recovery. On subsequent retesting at 85°K, the stress-strain curve was lower than that which would have been obtained if the specimen had not been warmed to room temperature. The softening of aluminum prestrained at 85°K, warmed to 194°K, and retested at 85°K should be less than the softening resulting from warming to room temperature. This softening effect also is indicated by the curves in Fig 12 and 13 for aluminum as presented by Dorn, Goldberg and Tietz. Fig 12 shows the effects of prestraining at 78°K on the true stress-true strain curves at 292°K. The slope of these curves is due to the combined influence of the ordinary strain hardening at room temperature and the room temperature softening following the previous strain hardening at the lower temperature.

The slope of these curves decreases as the amount of prestrain at 78°K increases. With extension to maximum load or necking these curves approach the curve obtained in the single stage test at 292°K. Fig 13 presents the effects of prestraining at 78°K on the true stress-true strain curves at 194°K. With extension to necking, however, these curves still remain considerably above the curve obtained in the single stage test at 194°K, indicating less softening than in the test results shown in Fig 12.

J. H. HOLLOMON*—Inherent to the problem of plastic deformation is the relationship between the effects of strain

introduced under differing conditions. In treating the engineering problem of materials, the simplest assumption that can be made with respect to prior strain history is that its effect is negligible if no phase transformations take place during the deformation. This assumption was made in the early part of this century by Ludwik and was justified by a few experiments. Other investigators have utilized the qualitative conclusions derived from this assumption in discussing and describing the effects of temperature and strain rate on the resistance to plastic flow. Certainly the notion permits a rationalization of such gross features of deformation as the relations between necking in tension and in creep tests.

On the basis of a few experiments on steels, I showed that the effects of prior strain history were exceedingly small. More recently, experiments have been performed by G. Sachs and E. J. Ripling* that are in almost complete agreement with my earlier experiments. It appears that particularly at low temperatures, and for ferritic steels, there is only a small effect of prior strain history even at large strains. On the other hand, the results of the authors show a pronounced effect of prior strain history. Orowan† has shown that the effect of prior strain history becomes progressively greater with increasing strain. The authors of the present paper have carried out a thoroughly competent investigation of the effect of strain history for their materials.

In Fig 18 of their paper, the authors show a difference in the equivalent strain depending on whether or not the specimen was first deformed at a high or a low temperature. Another equivalent strain may be definable that is independent of

*The Effect of Strain-temperature History on the Flow and Fracture Characteristics of an Annealed Steel. *Trans. AIME Vol. 185, 78, Journal of Metals*, Feb. 1949, 78.

* General Electric Co.

the sequence of the deformation temperatures. It seems reasonable that the shift in the stress strain curves should have been such as to make them asymptotic at large strains rather than identical at smaller strains. If the coincidence was assured at large strains, then the equivalent strains for the two sequences of temperature changes would have been nearly identical. There is some basis for defining an equivalent strain in this fashion. One would expect transient effects immediately upon reapplication of the load at the new temperature which would disappear with deformation at the second temperature.

Aside from such transient effects, the authors' experiments by themselves in no way invalidate the concept of the mechanical equation of state. The authors have simply shown either that there is no mechanical equation of state or that plastic strain is not an adequate measure of deformation. The self consistency of their results and an intuitive feeling with regard to the behavior of matter seem to require the latter conclusion. In order to demonstrate definitely that there is in fact little or no effect of prior deformation history when deformation is properly defined the following kind of experiment is necessary. Two specimens that are deformed the same amount (to the same equivalent strain in the authors terminology) must be deformed at some third temperature and their flow curves determined. If then these flow curves are identical, then the existence of a mechanical equation of state would have been demonstrated. Such a critical experiment is important to the further rationalization of the mechanism of deformation. It is conceivable that the equivalent strain if it does exist measures some fundamental properties of the material. Dr. D. J. McAdam,* and Dr. J. C. Fisher and I† have suggested that perhaps a proper measure of deformation fulfilling this condition is the stored internal energy. At a single temperature stored energy is probably a monotonic function of strain. However, this functional relationship may be different at different temperatures. Under such conditions, the work done during deformation may be a better measure of the stored energy. When the stress data of these investigators and of Orowan are plotted versus work, much less effect of prior strain history is noticeable.

Certainly the concept of equivalent strains is a good approximation to the way the authors' specimens behaved. If such equivalent strains are determined properly as can be done by investigations similar to the authors, and the significance of these equivalent strains is rationalized, a long step forward in un-

FIG 20—Effect of thermal prior strain history.

derstanding plastic deformation and predicting creep behavior would have been made. I fully agree with the authors that their data imply that at least for large strains all previous relations between the strength of metals and temperature are utterly confused by including both a variation in strength itself and a variation of the degree of deformation.

D. H. WOODWARD*—I would like to mention some results obtained at the National Bureau of Standards on the effect of thermal prior strain history. Curve A in Fig 20 was the type obtained at room temperature with the annealed material and curve B was the type obtained with the prior strained material. The schedule of prior straining was as follows: 1. The annealed material was extended 32 pct at room temperature. 2. The load was removed, the temperature raised, and the specimen deformed a small amount at a creep rate. 3. The load was removed, the temperature lowered to room temperature, and the flow curve obtained at that temperature. In such a case, not only is the shape of the latter flow curve different, that is, it is impossible to transpose it, but the resultant ductility is reduced.

J. H. HOLLOMON—That is 35 pct at room temperature, then heat it to what?

D. H. WOODWARD—Heat it to 350°F, that is, room temperature deformation followed by heating to 350°F. Deform a small amount in creep. Then complete the test at room temperature. The material was Monel.

E. J. RIPLING†—I should like to add here that there is no reason to suppose that results obtained on the fracturing characteristics after straining at two different temperatures are necessarily related to the flow characteristics under these conditions.

For example, work has been done at Case in which steel specimens were first

prestrained at room temperature and then tested at some lower temperature. These results, which should be published shortly, indicate the very complex behavior of the fracturing characteristics in a two-step test. When the retained ductility at the low temperature was plotted as a function of the prestrain conducted at room temperature, the curve possessed a very sharp minimum and maximum. However, the flow stress for these same specimens could be represented by a smooth curve always possessing a positive shape.

D. J. McADAM, JR.*—A few years ago, in my discussion of Dr. Hollomon's paper, "A Mechanical Equation of State," I referred to some experiments with aluminum, described in an earlier paper.²² These experiments showed that after aluminum has been plastically deformed at liquid air temperature, there is considerable relaxation when the metal is returned to room temperature. The results thus implied that an equation of mechanical state is not applicable to aluminum between room temperature and -188°C. At that time, I thought it possible that an equation of mechanical state might apply, throughout this temperature range, to metals with higher melting point, such as steel and nickel. However, in a paper published in August, 1947²³ we presented evidence that the flow stress for steels in liquid air is higher when the plastic deformation has been entirely at that temperature, than it is when part of the same total plastic deformation has been at room temperature. This evidence is found in Fig 6, 8 and 11 of that paper. Moreover, in Fig 2 of a paper published in Jan., 1948, we presented similar evidence concerning the flow stress of ingot iron.²⁴

During the last four months, I have studied the evidence in a series of our papers. The results have been assembled

* Presented as discussion at the Seminar on Cold Working, ASM, Philadelphia, 1948.

²² References are at end of discussion.

in 23 full page illustrations, and are discussed in a paper to be offered for publication by AIME. The results, like those presented in the paper by Dorn, Goldberg, and Tietz, show clearly that the rate of real work hardening increases with decrease in the temperature of flow. The results indicated that the conception of an equation of mechanical state is invalid.

J. E. DORN, A. GOLDBERG and T. E. TIETZ (authors' reply)—The authors wish to take this opportunity to thank Mr. I. Kramer of the Office of Naval Research for his competent oral presentation of this paper at the AIME meeting at Philadelphia, Oct. 26, 1948. They also express their appreciation to those contributing discussions to this paper, and are gratified to hear that the results of other workers are in substantial agreement with those given here.

The results reported in the text of this paper prove that the concept of equivalent strains is fundamentally untenable. The authors agree with Dr. Hollomon, however, that properly determined equivalent strains may possibly be of considerable practical usefulness for correlations of stress strain data obtained under various strain-rate and temperature histories. On the other hand it must be recognized that such correlations become acceptable only for small strains and that the concept of equivalent strains will not assist in arriving at a better understanding of work hardening.

The comments of G. W. Geil, N. L. Carwile and also Dr. D. J. McAdam on recovery of aluminum at room temperature after straining at liquid nitrogen temperature are appreciated by the authors. Recent tests on pure aluminum (99.987 pct) have shown that the rate of recovery at 90°F is approximately twice as great after straining at liquid nitrogen temperature as after straining at room temperature when the amounts of prestrain at liquid nitrogen and room temperature are so selected as to result in the same value of initial flow stress were the tests immediately continued at liquid nitrogen temperature.

In the present paper the authors reported a test in which a specimen of high purity aluminum was prestrained at room temperature and then tested at liquid nitrogen temperature. From the data given in Fig 14, it is evident that the flow stress for pure aluminum tested at liquid nitrogen temperature after 0.15 prestrain at room temperature falls about 9,000 psi below that obtained when the specimen is strained the same amount at liquid nitrogen temperature. The amount of recovery which occurred after prestraining at room temperature before continuing the test at liquid nitrogen has been determined from a series of recovery tests to be not more than 400 psi, accounting for only a small part of the difference noted. Although recovery of high purity aluminum does occur at atmospheric temperature, such recovery

cannot account for the observed failure of the so-called "mechanical equation of state."

Any possible recovery of 2S-0 at atmospheric temperature after prestraining at liquid nitrogen temperature would have decreased the observed difference between the flow stresses of Fig 12 at room temperature. In the absence of recovery, therefore, somewhat greater effects of the past strain history would have been obtained than those recorded in Fig 12. The observed effects of past strain history on the flow stress described in this paper therefore are only slightly affected by recovery. The conclusion that the postulated "mechanical equation of state" is incorrect appears to be inescapable.

The Room and Elevated Temperature Properties of Some Sand Cast Magnesium-base Alloys Containing Zinc

By T. E. LEONTIS, Junior Member AIME

DISCUSSION

(P. R. Kosting and W. A. Johnson
presiding)

JAY R. BURNS*—The presentation of this paper represents another significant advance in the field of magnesium metallurgy. The higher creep strength of the magnesium-zinc base alloys should place these materials in many applications which stand waiting.

Dr. Leontis has shown a comprehensive picture of the relative merits of many conceivable magnesium-zinc base alloy compositions. Work in the Materials Laboratory has substantiated the good properties obtained from such alloys at

room temperature although no elevated temperature testing has been done. One factor which has been evident in the work, however, is the tendency of these alloys to produce a dirty casting. Apart from the microporosity, small oxide skins appear prevalent in cast test bars. The proper use of screens and steel wool obviated the difficulty in the bars but some difficulties might be expected in larger castings. The presence of zirconium was found to emphasize the difficulties of obtaining sound and clean bars whereas Mischmetal reduced the trouble.

Certain other investigators have reported yield strengths of about 28,000 psi and corresponding elongations of 6-8 pct for magnesium-zinc-zirconium alloys. The Materials Laboratory has also obtained such figures from these alloys but the number of tests has not been very large. I should like to ask the author if he

believes the figures 24,000 psi and 3 pct for yield strength and elongation are more in line with the typical figures for the alloy.

T. E. LEONTIS (author's reply)—The comments of Mr. Burns are most welcome.

In regard to the tendency of magnesium-zinc alloys to produce dirty castings, I cannot say that we have had the same experience. The binary alloys and all the ternary alloys with which we have worked, except those containing zirconium, do not require any more special treatment than either of the two commercial magnesium sand-casting alloys, AZ63 and AZ92, to produce clean castings. It is true that zirconium does introduce more flux, oxide skins, and nonmetallic inclusions, but here again, either by careful flux treatment and settling or by proper chlorination, clean

FIG 26—Tensile properties at room temperature for binary Mg-Zn alloys.

castings can be made. We have not experienced any more difficulty in making clean castings of production size than in making clean test bars.

Certain differences also exist between our observations on the microporosity of Mg-Zn alloys and those of Mr. Burns. Binary magnesium-zinc alloys have a high porosity tendency. This tendency is most markedly reduced by the addition of Mischmetal as Mr. Burns states, but we have observed that the addition of zirconium or any of the other elements investigated, with the exception of manganese, also reduces the microporosity to the point where relatively sound castings can be produced. The soundness of these castings compares favorably with that of AZ63 alloy. Alloys containing 0.7 to 2.0 pct manganese, on the other hand, produce very porous castings.

In reply to Mr. Burns' question about the mechanical properties, I do not believe we are in a position as yet to say what the typical properties of Mg-Zn-Zr alloys are. I am assuming that the properties which Mr. Burns has cited refer to an alloy containing 5 to 6 pct zinc and 0.7 pct zirconium. We have also seen 28,000 to 30,000 psi yield strengths and 6 to 8 pct elongations in certain batches of this composition. I used the somewhat lower figures in this paper because those were the room temperature properties of the batch on which I also had elevated temperature data. I consider that these properties are related directly to the grain size. Whether one obtains 28,000 psi, and even higher, or 24,000 psi, and

somewhat lower, depends on whether the grain size is 0.002 to 0.004 in. or 0.007 to 0.014 in., respectively. The control of the grain size of these alloys, particularly in production size castings having sections of varying thickness, is a problem that requires considerable further investigation.

J. W. MEIER*—The paper by Dr. Leontis covers a very wide field and represents a considerable amount of experimental work. The author is to be congratulated for his effort and the presentation of the results.

Experimental work on higher strength magnesium alloys at the Canadian Bureau of Mines included also many alloys based on the Mg-Zn system. Since most of our work is still not published, I would like to mention only some of the results which differ from the data presented by Dr. Leontis.

Our results of tensile properties at room temperature for the binary Mg-Zn alloys, both in the "as cast" and the "HTA" conditions, show (Fig 26) an increase of UTS for the zinc range of 8–11 pct to over 30,000 psi and over 40,000 psi respectively, with elongations of 7–8 pct.

These results are based on alloys prepared from high-purity magnesium and electrolytic zinc, without any manganese additions.

The mechanical properties at room temperature for Mg-Zn-Zr alloys, reported by the author, would seem to be somewhat lower than average results

achieved in our investigations. As already reported* "as cast" ZK61 alloy test bars showed average UTS of 38–40,000 psi, 0.2 pct PS of 20–22,000 psi and elongations over 10 pct. Grain sizes of the Mg-Zn-Zr alloys, shown in Table 2, reveal that the "effective" zirconium content in alloys 18–24 was rather low. Our investigation showed that the best mechanical properties in these alloys can be achieved only if the zirconium content is well above 0.7 pct and the average grain size is in the range of 0.001–0.002 in., in any case below 0.003 in.

Special heat treatment cycles were established for these alloys which increased considerably the mechanical properties without any effect on the grain size. Maximum results on fully heat treated ZK61 alloy castings of 48,000 psi UTS, of 35,000 psi 0.2 pct PS, and of 7–12 pct elongation were achieved. Considering the strength-to-weight ratio, these alloys have tensile properties superior to any aluminum casting alloys.

Another interesting characteristic of the Mg-Zn-Zr alloys is room temperature aging. "As cast" test bars, stored for some time at room temperature, show considerable increase of proof stress and hardness, as well as some increase of the UTS. Although a more systematic study of this problem is still under way, it may be said that increases of UTS up to 3,000

FIG 28—Same as Fig 27, risers sectioned to reveal internal porosity.

psi, and of 0.2 pct PS up to 6,000 psi, have been found.

The effect of calcium additions to Mg-Zn-Zr in the range of 4-6 pct Zn was found to be detrimental to the tensile properties causing a considerable decrease of both the UTS and the elongation.

H. S. SPENCE*—This paper is a valuable contribution to the growing literature of magnesium and its alloys and the author is to be congratulated on both the work accomplished and its presentation.

There is one point which has been mentioned very briefly but which has important practical significance. This concerns the sensitivity to porosity of the binary magnesium-zinc alloys. Mr. Leontis states, in part, "Binary alloys containing more than 2 to 3 pct zinc . . . have a high porosity tendency. . . . All other binary and polynary alloys investigated were essentially free of porosity." Is it correct to infer that the binary magnesium-zinc alloys below 2-3 pct zinc were found to be essentially free of porosity?

It is stated that all alloy melts were prepared according to the 'crucible method' described by Nelson. Was any degassing attempted in the high zinc binary alloys using chlorine or any other agent?

Personal experience in alloying experiments confirms the findings of greater susceptibility to porosity in the higher zinc content binary alloys. This is certainly true with reference to hydrogen and the sensitivity in the range 2 to 6 pct zinc appears to be a function of zinc content. Fig 27 and 28 show this effect quite clearly; these illustrate risers cut from test bar castings from three melts containing respectively 1.89, 3.98 and 6.02 pct zinc. To each melt was added an identical quantity of hydrogen in the form of a metal hydride. The effect of zinc content in repressing the solid solubility of hydrogen is evident. Flushing similarly prepared melts with chlorine did not prove satisfactory in eliminating the hydrogen, even when using a quantity and treatment time in excess of that consistent with practical considerations.

Returning to Dr. Leontis' paper, it is interesting to note that his work does not

confirm earlier published data (J. A. Gann,⁶ National Physics Laboratory,⁶ P. Spitaler⁷) which indicate a fairly sharp maximum UTS of as-cast binary Mg-Zn alloys somewhere in the range between 4 and 6 pct zinc. While the earlier workers were not in agreement as to maximum UTS or its corresponding per cent zinc, all three curves indicated a definite maximum as opposed to the findings now reported which show a constant UTS over the range from 2 to 7 pct zinc. Does the answer to this difference lie in the number of determinations made in the present work with the consequent elimination of erratics, or is it in variations in the foundry techniques used by the different investigators? I suggest it may be the latter since, as these alloys respond to heat-treatment, varying cooling rates after casting may produce effects equivalent to different degrees of partial heat-treatment.

M. W. MARTINSON*—This paper has been a valuable contribution to the magnesium industry, particularly to

⁶ References are at end of discussion.

those associated directly with the development of new and better alloys and should serve as a basis for the further study of magnesium base alloys containing zinc, zirconium and rare earths.

Mr. Leontis states that, "The addition of 3 pct cerium added to Mg-3Zn improves the strength properties at 300 and 400°F, but is detrimental to room temperature strength. The addition of 3 pct zinc to Mg-3Zn to make Mg-6Zn alloy, however, results in still higher properties at elevated temperatures than those of the alloy containing cerium, and at the same time, is beneficial to the strength at room temperature."

Reviewing the creep data presented for these alloys we find that Mg-3Zn-3Ce is considerably superior to Mg-6Zn at both 300 and 400°F at all loads tested.

Early in our investigations carried out at the Canadian Bureau of Mines in Ottawa, we concluded that zinc had the advantage of raising the mechanical properties of magnesium base alloys intended for elevated temperature use up to 300°F, but above this temperature its presence was detrimental, particularly increasing the creep rate of these alloys.

This raises a question. From the engineering point of view, at what point does the author consider tensile properties to be overshadowed by creep properties in the final evaluation of a magnesium base alloy for elevated temperature use?

In the making of the various magnesium base alloys containing cerium and zirconium: 1. Was it necessary to degas the melt in any manner before or after the zirconium chloride fused salt addition, or was the refining effect from the fused salt mixture sufficient? 2. To what degree did a varying iron content in the Mischmetal added affect the final zirconium analysis? 3. Could the author give an idea of the initial alloying efficiency to be expected for both the rare earths and zirconium additions? 4. What recovery of rare earths and zirconium can be expected on remelt, and what methods are used to revivify the rare earths and zirconium losses to restore the initial properties of the alloy?

C. J. P. BALL*—My metallurgical staff and I were greatly interested in the paper by Mr. Leontis and I attach some detailed comments by my staff upon certain points in which they are particularly interested. Since Mr. Leontis touches upon the development and usage of magnesium-zirconium alloys, I think you would be interested to learn the present position in the United Kingdom as regards the magnesium-base casting alloys containing zinc and zirconium with and without Mischmetal.

At our Clifton Junction works we have carried out, over a number of years, a considerable volume of research and develop-

ment work on these zirconium-containing alloys. Two major problems presented themselves, and both had to be solved at a reasonable cost. The first was the introduction of sufficient zirconium in effective form without serious chloride contamination, the second, the suppression of microporosity, which has always presented a danger with all forms of magnesium alloys, and which can also ruin castings in high strength zinc-zirconium containing alloys unless the correct technique is used.

I am glad to say that special alloying compounds and fluxes have been evolved by my company, which enable the alloying to be carried out simply and at a reasonable cost, with no danger of flux contamination, and which yield a zinc-containing alloy virtually free from microporosity even in the thickest sections. As a result this alloy, Z5Z, (4.5 pct zinc, 0.7 pct zirconium) is being called for in rapidly increasing quantities for many structural castings, particularly in the aircraft industry. The properties of the casting are remarkably uniform, and frequently exceed those of separately cast test bars. Because of the ease with which this alloy can be handled in the foundry and the superior mechanical properties at room temperature, it is expected that this alloy will replace the greater part of the magnesium-aluminum-zinc alloys at present used for structural purposes.

The advances made recently in the magnesium-base alloys containing Mischmetal in addition to zirconium and zinc have been most striking. Because of their resistance to creep at temperatures around 200°C, their main applications so far have been elevated temperature work. The ZRE1 alloy (2.7 pct zinc, 2.7 pct Mischmetal and 0.7 pct zirconium) has made particular progress. Its properties at room temperature are—

| | |
|------------------|-------------|
| Yield | —14,000 psi |
| Tensile strength | —23,000 psi |
| Elongation | —5 pct |

Around 200°C its resistance to creep is practically identical with that of RR.50, the well-known general-purpose aluminum-base alloy widely used in the United Kingdom for service at elevated temperatures. Incidentally, the tensile strength of 15,000 psi given in the recent American Specification AMS.4428 would seem to compare most unfavorably with the corresponding figure for ZRE1, particularly since the small margin of 2,000 lb only between tensile and yield indicates the inherently brittle nature of this alloy at room temperature in the cast state.

Practical experience in the fabrication of the largest and most complicated castings, even as high as 900 lb net weight, has proved conclusively that the ZRE1 alloy containing not less than 2 pct Mischmetal is inherently free from any tendency to microporosity.

This concludes my short resume of the development and present position of the

magnesium-zirconium-zinc and magnesium-zirconium-zinc-Mischmetal alloys in this country.

Writing as a member of the AIME, it is my hope that this survey will be found of interest to Mr. Leontis and to those who have taken part in the discussion.

As we understand that considerable work on magnesium-zirconium-zinc and magnesium-zirconium-zinc-Mischmetal alloys is also being carried on in the U.S., perhaps some of the members taking part in the discussion would be able to answer the following questions: 1. Are magnesium-zirconium containing castings now being produced readily free from flux inclusions? 2. Can large castings be made readily in magnesium-zinc-zirconium free from microporosity? 3. Are alloys of magnesium-zirconium-zinc-Mischmetal readily available to the trade?

A. C. JESSUP* and J. B. WILSON*—Mr. Leontis has presented extensive data on magnesium alloys, and since his paper summarizes the properties for many alloys for which published values are not otherwise available, it provides most interesting reading for all workers in the magnesium industry. The article is, however, a little difficult to follow, and the comments and figures occasionally appear somewhat contradictory, nor do we in all cases agree with the inferences which have been drawn.

For instance, Fig 29 shows the effect of adding calcium in amounts up to 1 pct to a Mg-Zn-Zr alloy; in our opinion this shows calcium to be positively injurious. We would agree that the addition of cerium produces a similar reduction in room temperature properties, but for high temperature service the advantage of enhanced creep resistance more than outweighs the disadvantage of lower room temperature properties.

On p. 19 of his paper, the author claims that the Mg-6Zn-0.5Mn alloy is comparable for strength and ductility at all temperatures with the Mg-6Zn-1Zr alloy, and quotes Fig 10. We are not able to substantiate this sweeping statement. While we do not recommend the use of Mg-Zn-Zr alloys at temperatures above 300°F, and favor a lower Zn content, our experience based upon hundreds of tests and many tons of production, has satisfied us that the room temperature properties of a Mg-4.5Zn-0.7Zr alloy when prepared with the proper alloying reagents are certainly higher than the author quoted for Mg-6Zn-0.5Mn at room temperature. In Fig 10, the room temperature properties of the manganese containing alloy are given as:

| | |
|------------------|-------------|
| Yield | —24,000 psi |
| Tensile strength | —38,000 psi |
| Elongation | —5 pct |

* Magnesium Elektron Limited, London, England.

* Magnesium Elektron Limited, Clifton Junction, Manchester, England.

FIG 29—Effect of adding calcium in amounts up to one per cent to Mg-Zn-Zr alloy.

Comparable properties for a Mg-4.5Zn-0.7Zr alloy when tested as an unmachined "American" type test bar, after an annealing treatment of 10 hr at 350°F, are:

Yield —27,000 psi
Tensile strength—40,000 psi
Elongation —5 pct

Moreover, pronounced freedom from microporosity and grain coarsening on heat treatment, and small variation in mechanical properties between test bars and specimens cut from the casting, make this alloy particularly attractive to the foundryman. We have not had much experience with the 6 pct zinc-0.5 pct manganese alloy, but such as we have had has shown it to be even more microporous than AZ92, which in turn suffers much more from microporosity than the 4.5 pct zinc-0.7 pct zirconium alloy.

The improvements offered by the Mg-Zn and similar alloys over the AZ92 and AZ63 alloys are noted with interest. We feel, however, that the all-round properties of these alloys do not offer to magnesium founders the great advances and improvements in properties and casting techniques which they can obtain from the Mg-Zr-Ce alloys developed by Murphy and Payne or from the alloys of Mg-Zn-Zr-Ce, designated ZRE1 and ZRE2, recently developed in the United Kingdom by Magnesium Elektron

Ltd. These latter contain nominally Mg-2.7Zn-0.7Zr-2.7Ce and Mg-4.5Zn-0.7Zr-2.0Ce, respectively. Mr. Leontis has tested two closely similar compositions (his alloys 28 and 30) and finds them among his most promising alloys at 300°F. It was surprising to find therefore, that he did not investigate this type of alloy in more detail at 400°F, particularly in view of their extremely attractive combination of properties over the 60–400°F range. In Fig 30, we have plotted several of the author's results from Tables 6 and 7 at 300 and 400°F and have added a few of our own obtained at 400°F. In this diagram we consider *creep rates* only, since, in our opinion, the use of an arbitrary "creep limit" is likely to prove misleading.

Our results include the ZRE1 and ZRE2 alloys and also the Mg-3Ce-0.7Zr composition (MCZ) as developed by Murphy and Payne. We find that there is little to choose between the MCZ and ZRE1 alloys over the 60–400°F range of temperatures. The zinc containing alloys are, however, distinctly easier to handle in the foundry. The superiority of the cerium bearing alloys at 400°F requires no comment.

The author states on p. 29 and 31 of the paper that zinc lowers the creep resistance of Mg-Ce alloys. This may well be true in the particular case of zinc

additions to the binary Mg-Ce alloy. However, all our experience has shown both in tests and in practical foundry production that if the full amount of effective zirconium is present, considerable amounts of zinc may be tolerated without adverse effect upon creep resistance. This is demonstrated by Mr. Leontis' own experience with compositions 28 and 30 and our experience with the alloys ZRE1 and ZRE2. This may be due to the suppression of the formation of zinc phase when zirconium is present, which would in turn prevent the "dilution" of the cerium compound by zinc compounds at the grain boundary, and would enable it to act as if the zinc were absent. If Mr. Leontis did not find the Mg-Ce-Zn-Zr alloy quite as satisfactory as the Mg-Ce binary for creep, then judging from the results he quotes for other zirconium containing alloys, it would seem to be probable that his results are unsatisfactory because he has not been able to introduce into his alloy the necessary amount of effective zirconium to counteract the zinc.

In conclusion, we should like to record that these differences of experience and interpretation apply only to a small part of the paper, the majority of which is entirely in accord with our own work and experience.

T. E. LEONTIS (author's reply)—It is

FIG 30—Plot of results from Tables 6 and 7 at 300° and 400°F, and others at 400°F.

gratifying to see that this paper has aroused so many interesting discussions from our friends in Canada and Great Britain. In the following, I shall attempt to present briefly my views on the many questions raised by the various contributors.

Mr. Meier and Mr. Spence have mentioned the properties of binary Mg-Zn alloys. It is interesting to note that the tensile yield strength of their alloys both in the as-cast and in the heat treated and aged condition, as shown in Fig 26 of Mr. Meier's discussion, are in reasonably good agreement with the values given in Fig 6, particularly if the curve for the heat treated and aged condition is drawn through all the points as is done in Fig 6. In regard to the tensile strength, if one looks at the experimental points rather than the curves drawn in Fig 26, again the agreement is good between the two sets of data up to 7.5 pct zinc. The absence of a sharp maximum in this property between 4 and 6 pct zinc that was observed by earlier investigators, as mentioned by Mr. Spence, is noted also in Fig 26. The markedly higher values de-

picted by Mr. Meier's results in alloys containing 8 to 11 pct zinc must be associated with differences in foundry practice. Perhaps the conditions of preparing the alloys were such as to result in a finer grain size and, what is more important in alloys containing a large amount of zinc, in a finer distribution of the intermetallic compound. Other factors that also may affect the tensile strength of Mg-Zn alloys have been cited by Mr. Spence. In reply to the question about the porosity of binary Mg-Zn alloys, my observations of freedom from porosity in alloys containing up to 2-3 pct zinc were made on cast test bars. The evidence that Mr. Spence has presented indicates that difficulty can be expected in larger casting even in the lower zinc contents. Attempts made to minimize porosity in Mg-6Zn alloy by chlorination have not been very successful.

In line with the observations of Mr. Burns, Mr. Meier has reported some still more spectacular properties for cast ZK60 alloy. Their high strength and ductility values are associated undoubtedly with the very fine grain size that Mr.

Meier was able to achieve in his alloys. As he has noted, in many of the alloys in the paper the zirconium content mentioned is below 0.7 pct, an amount which he feels must be exceeded in order to attain the finest possible grain size. However, alloys prepared recently in which the zirconium content exceeded his minimum have not confirmed his findings either with respect to grain size or properties.

Turning to the comments of Major Ball concerning Mg-Zn-Zr alloys, I was very interested to hear of his successful application of these alloys in the foundry. We have been successful in producing certain castings in ZK60 alloy free from flux, porosity, and cracking. The flux problem can be eliminated by proper treatment as discussed above. However, difficulties are sometimes encountered with porosity and cracking when more intricate castings are made from this alloy. The ingredients for making up these alloys are freely available in the United States on the open market.

The question of room temperature strength vs. elevated temperature strength and creep resistance raised by

Table 10 . . . Comparison of Alloys

| Temp. °F | Mg + 6Ce | | | Mg + 3Ce | | | Mg + 3.1Zn + 2.7Ce + 0.45Zr | | |
|----------|----------|----------|------|----------|----------|------|-----------------------------|----------|------|
| | Pct E | TYS | TS | Pct E | TYS | TS | Pct E | TYS | TS |
| | | 1000 psi | | | 1000 psi | | | 1000 psi | |
| Room | 1.0 | 17.0 | 20.4 | 1.5 | 12.4 | 20.5 | 3.8 | 13.4 | 22.3 |
| 300 | 2.0 | 14.9 | 19.3 | 7.0 | 12.9 | 17.9 | 14.4 | 11.9 | 21.7 |
| 400 | 2.0 | 14.7 | 18.6 | 4.7 | 11.9 | 16.8 | 19.8 | 11.6 | 18.4 |
| 500 | 4.0 | 13.4 | 17.9 | 11.7 | 11.3 | 17.9 | 44.0 | 9.7 | 14.4 |
| 600 | 12.5 | 9.8 | 14.3 | 24.2 | 8.8 | 13.5 | 66.5 | 6.7 | 9.1 |

The data are self-explanatory.

Mr. Martinson is one which is frequently asked but it is not answered very often, at least not to the satisfaction of designers and engineers. Certainly, if a part is to be exposed to sustained loads of predetermined value at elevated temperatures, the resistance to creep at those temperatures would necessarily be the controlling factor in design. However, it is always necessary to make provision for overloading which may occur during operation or during assembling of the part. For this reason, it will be found that the highest possible static properties are desired both at room temperature and at elevated temperatures in order to reduce failures to a minimum. Thus, in the selection of an alloy for elevated temperature service, a compromise may have to be made between static properties and creep resistance. The answers to questions of Mr. Martinson concerning foundry practice are as follows: 1. This has been answered adequately in reply to Mr. Burns' discussion. 2. We have no data from a systematic investigation of this effect. There unquestionably is a lowering of zirconium content resulting from the introduction of iron when Mischmetal is added to the melt and it certainly would be expected that the degree of lowering will be dependent on the amount of iron added. 3. The initial alloying efficiencies of rare earths and zirconium are:

Pct
Rare earths..... 80-90
Zirconium..... 20-40
4. The losses of rare earths and zirconium in absolute amount upon remelting are approximately:

Pct
Rare earths..... 0.5
Zirconium..... 0.1-0.2
The revivification of rare earths and zirconium is accomplished by adding the amount lost after remelting. The additions are made on the basis of the alloying efficiencies given above.

The discussion of Messrs. Jessup and Wilson contains many interesting points, some of rather controversial nature. I was interested to see their results on the effect of calcium on the properties of Mg-4.5Zn-0.7Zr alloy. It will be noted in the paper that the claim for an enhancement of the properties by the addition of 0.3 pct calcium was made only for the

composition Mg-1Zn-0.7Zr. Fig 9 of the paper shows that the same addition of calcium to Mg-3.5Zn-0.7Zr results, if anything, in a slight decrease in room temperature tensile strength. It is apparent from these data and those of Messrs. Jessup and Wilson that the effect of a small addition of calcium to these alloys depends upon the zinc content; at low zinc contents there is an increase in strength which appears to go through a maximum between 0 and 3 pct zinc, and at zinc contents above 3-3.5 pct zinc there is a definite decrease in strength resulting from the calcium addition.

The properties of Mg-6Zn-0.7Zr (ZK60) and Mg-6Zn-0.5Mn (ZM60) are more readily compared in Table 9. With the data available at the time of the writing of the paper, I cannot see any great differences between the properties of the two alloys with the exception of the somewhat lower ductility of ZM60 at 300 and 400°F. It is true that higher strengths can be attained in ZK60; in fact, considerably higher properties than those cited by Messrs. Jessup and Wilson have been shown by Mr. Meier. As for the foundry characteristics of the two alloys, the statements made in the paper were based on observations from the casting of test bars and a few relatively simple castings. Since the writing of the paper, more extensive tests on the foundry characteristics both of ZK60 and ZM60 have shown that the latter alloy has a much greater porosity tendency in larger castings than the zirconium-containing alloy.

Both Major Ball and Messrs. Jessup and Wilson have indicated that for elevated temperature service they would favor an alloy of the Mg-Zn-Ce-Zr type. It has been the thesis of this paper that Mg-Zn-Zr alloys offer a combination of room temperature properties equivalent to those of the present Mg-Al-Zn commercial alloys and significantly higher creep resistance at elevated temperatures than the commercial alloys. Mg-Al-Zn alloys have been used widely in parts exposed to temperatures up to 300°F. With the higher resistance to creep of the Mg-Zn-Zr alloys, there is every reason to believe that these alloys would be satisfactory in many parts operating at temperatures as high as 400°F.

For applications at temperatures above 400°F, we in the United States have been recommending Mg-Ce alloys. Major Ball's comparison of the laboratory properties of ZRE1 alloy with those of E6 (Mg + 6 pct Ce) alloy as specified in AMS4428 is not proper. Specified minimum properties are always set lower than typical values. A more realistic comparison can be made by using laboratory data for both alloys. This is done in Table 10 where the properties of an alloy having an analysis similar to that of Major Ball's alloy and those of two Mg-Ce alloys are presented over a wide temperature range. All these alloys are in the heat treated and aged condition.

It is the contention of Messrs. Jessup and Wilson that the elevated temperature creep resistance of Mg-Zn-Zr-Ce alloys is equivalent to that of the Mg-Ce alloys. Since the writing of the paper a few alloys of the former type have been tested in creep at 400°F. The results of these tests together with the corresponding properties of two Mg-Ce alloys are tabulated below. All the alloys were tested in the heat treated and aged condition. In order to present a complete picture, the creep limits based on three levels of extension are given in Table 11: (1) 0.1 pct creep extension, (2) 0.2 pct total extension, and (3) 0.5 pct total extension. I prefer the use of a creep limit based on a specified amount of extension to the use of an actual creep rate for several reasons. In the first place, a creep limit can be used directly in design calculations. Secondly, during creep tests of short duration, the creep rate very often does not attain a constant value. Thus, such creep rates are unreliable for predicting behavior in practice. It can be seen from the above summary that the best creep resistance is offered by Mg + 6 pct Ce alloy. This fact, coupled with the superior strength of this alloy at elevated temperatures, renders the material more attractive than the Mg-Zn-Ce-Zr alloys for applications up to 600°F. On the basis of the above data, particularly the stress values for 0.2 and 0.5 pct total extension, it appears that the alloy ZRE1 approaches the creep resistance of Mg + 3Ce. Inasmuch as Messrs. Jessup and Wilson have presented only creep rates in

their discussion, it would be interesting to compare their figures with those obtained in the present tests. The values for the Jessup and Wilson alloys given in Table 12 were taken from their Fig 30. There are apparently wide discrepancies between the two sets of data. If creep rate were used exclusively for evaluating the creep characteristics of the alloys, the present author's results indicate a very significant superiority of the Mg + 3Ce alloy over the zirconium-containing alloys.

There is one factor that has not been considered as yet. Whereas all the results that I have presented were obtained on alloys in the heat treated and aged condition, there is no mention of any heat treatment made by Messrs. Jessup and Wilson. Presumably, all their tests were performed on material in the as-cast or in the as-cast plus aged condition. At the present time, I have creep data available on Mg + 4.4Zn + 3.7Ce + 0.55Zr at 300°F in both conditions. These are presented in Table 13 together with the corresponding information for Mg + 3.23Ce. On the basis of creep limits there is little to choose between the two conditions of heat treatment, but the creep rates show the ACA condition to render the alloys somewhat more resistant to creep. The Mg-Ce alloy is again superior to the zinc-containing alloy both on the basis of creep limits and of creep rates in spite of the somewhat lower cerium content. This information indicates that the lower creep rates reported by Messrs. Jessup and Wilson may be attributed to their testing the alloys in the ACA condition. However, this emphasizes the hazards of using only the creep rate in evaluating alloys for elevated temperature service. Inasmuch as the total extension obtained is the same in both cases, the lower creep rate of the alloys in the ACA condition means that more of the extension is obtained during loading and less during the creep test.

It has been proposed that perhaps the lower resistance to creep of the Mg-Zn-Ce-Zr alloys used in the present paper may be due to our inability to introduce a sufficient amount of zirconium in our alloys. The zirconium content of most of my alloys is admittedly lower than that claimed by Messrs. Jessup and Wilson as being necessary for attaining the highest possible creep resistance. However, reference to Table 1 in the paper shows that alloy No. 28 has the lowest zirconium content of the cerium-containing alloys and at the same time has been shown to have the highest creep resistance. In fact, the creep rates of the alloy with no zirconium given above are lower than those of either of the two zirconium-containing alloys. The data show that high creep resistance is associated with a high Ce/Zn ratio emphasizing again the predominant position of cerium in magnesium alloys for elevated temperature

Table 11 . . . Creep Limits Based on Three Levels of Extension

| Alloy | Creep Limit — 1000 psi (400°F) | | |
|------------------------------------|--------------------------------|-----------------------------------|-----------------------------------|

creep resistance. As for the necessity of the presence of zirconium to suppress the formation of the zinc intermetallic compound, it has been my observation that even small amounts of cerium alone added to alloys containing up to 6 pct zinc will produce this effect.

In conclusion, only time and further experience can settle current differences of opinion on the preferred magnesium alloys for either room or elevated temperature service. Relative costs based on the alloying elements used, and the foundry efficiencies attained, will certainly be a factor. At elevated temperatures, the actual temperature concerned, and the appropriate creep strengths in the best condition of heat treatment, will affect the decision. An urge for simplicity in foundry operations may result in a compromise of a few alloys of good average properties, rather than more alloys each with its specialized field of use.

I would like to thank all the contributors to the discussion of this paper for their stimulating comments and criticism. I shall be looking forward to seeing the results of their investigations in formal papers.

The Low Temperature Properties of Tin and Tin-lead Alloys

By H. S. KALISH and F. J. DUNKERLEY, Junior Members AIME

DISCUSSION

(P. R. Kostling and W. A. Johnson
presiding)

R. I. JAFFEE*—I should like to amplify the work of Kalish and Dunkerley on the basis of some work we did in conjunction with the National Lead Co. about three years ago, which is to be published in *Metal Progress* early in 1949.

In general, we confirmed the statement that 50-50 lead-tin is brittle at low temperatures. However, we investigated the lead-rich range, and found, as might be expected, that the lead plus $2\frac{1}{2}$ pct silver alloy and lead-rich lead-tin alloys had rather good low temperature properties, both in ductility, strength, and in Charpy impact values.

One observation made on alloys between the high tin range investigated by Kalish and Dunkerley and the high-lead range was that alloys with about 15 pct tin did not decrease materially in impact strength or in ductility, as temperature went down to -295°F . This point, it seems to us, should be emphasized, since the presence of tin, at least up to 15 pct, in a lead-tin solder is rather important for commercial applications because of the improvement tin makes in solderability and wetting power.

J. R. LOW, JR.†—The authors have presented a very interesting paper and one of the few describing a systematic investigation of the relationship between microstructure, composition and low-temperature brittleness in a series of alloys.

The only comment I should like to make is that I believe the use of the term "ultimate tensile strength" over the full range of the curve so labelled in Fig 3 of

the paper is misleading. As far as engineering design is concerned, this is a valid use of the term; however, in thinking about the mechanical properties of the metal, a distinction should be made between the quantity measured above and below the transition temperature. Above the transition temperature the ultimate tensile strength is a measure of the stress at which necking begins and is therefore related to the rate of strain hardening. Below the transition temperature, the fracture strength of the metal is being measured. For this reason the maximum ultimate tensile strengths referred to throughout the paper are in a sense fictitious maximums.

H. S. KALISH and F. J. DUNKERLEY (authors' reply)—The authors wish to thank Drs. Jaffee and Low for their comments on this paper. From the results reported here, we would predict a lead-silver alloy containing $2\frac{1}{2}$ pct silver would remain ductile at low temperatures and we are glad that Jaffee's work confirms this as well as our other work on the tin-lead alloys. It might further be speculated in agreement with Brick and Seigle¹⁶ that any alloy formed by the combining of any two or more face-centered cubic metals, such as silver and lead, should remain ductile to absolute zero.

The superior ductility of the 85-15 lead-tin alloy is indeed important as emphasized by Dr. Jaffee. Again this would be predicted if the T_B curve of Fig 11 were extrapolated to higher lead contents. Kostenets¹⁷ found that a tin-lead alloy containing 25 pct tin still remained ductile at -253°C , only 20°C above absolute zero.

We agree with Dr. Low that it would have been desirable to separate the so-called ultimate tensile strength above T_B

from that measured quantity below T_B . However, since we did not have true stress-strain, yield strength, work hardening moduli and other fundamental data available, we were not able to separate all the variables quantitatively and preferred to present the engineering tensile data in the form most useful to engineers. These necessary fundamental data, however, are being obtained in this laboratory so that a more rigorous analysis of these low temperature properties can ultimately be made.

Dr. Low is quite right that the rate of strain hardening is the most important factor in determining the tensile strength above T_B , while below T_B the fracture strength is the main component. In neither case, however, is the strain hardening or the fracture stress, respectively, the only component. For example, the ultimate tensile strength, Fig 3, could not be labelled fracture strength below T_B because considerable ductility remained to make an appreciable work hardening contribution to the tensile strength feasible. The necessary qualitative rationalizations of the tensile data of this survey report should be clarified and amplified by the forthcoming fundamental data currently being obtained in this laboratory.

Thermal and Electrical Properties of Ductile Titanium

By E. S. GREINER and W. C. ELLIS, Members AIME

DISCUSSION

(P. R. Kostling and W. A. Johnson
presiding)

P. DUWEZ*—We would like first to

congratulate the authors for a very interesting piece of work on a difficult subject. We have been studying the thermal expansion of pure titanium for some time and have found the coefficient of expansion between room temperature and

800°C to agree closely with the value given by the authors. We are particularly interested, however, in the thermal expansion anomalies accompanying the $\alpha \rightleftharpoons \beta$ allotropic transformation.

On specimens machined out of a bar

* Jet Propulsion Laboratory, California Institute of Technology.

manufactured by the vapor deposition process (obtained from Foote Minerals) we have observed a contraction on heating and an expansion on cooling, both around 880°C. The change in length varied somewhat from sample to sample, but was about 0.05 pct. This anomaly in the expansion curve was almost negligible on heating and completely absent on cooling when the bar was cold worked (reduction of area about 30 pct) before the test. The same experiments made on sintered titanium (from Bureau of Mines powder) did not reveal any thermal expansion anomalies.

We would like to ask the authors if they have made any measurements of thermal expansion across the α , β critical temperature and we would appreciate very much their comments on the subject.

W. C. ELLIS and E. S. GREINER (authors' reply)—The discussion by Professor Duwez of the volume changes in the 885°C transformation as evidenced by linear expansion measurements is particularly interesting and the additional data are welcomed. The authors made similar measurements on Bureau of Mines titanium (magnesium-reduced) but did not report the results in the paper because of uncertainty as to their significance. In these experiments there was always a volume decrease on heating through the transformation but no detectable discontinuity on cooling. The result was a shortening of the specimen as it was cycled through the transformation. The cause of the shortening was tentatively assigned to a further sintering of the expansion specimen in traversing the transformation. This was possible since the expansion specimen was only approximately 75 pct reduced in area from the sintered compact and could reasonably be expected to contain a distribution of fine voids.

Sintering of the expansion specimens during test in the temperature range below 800°C, for which data were given in the paper, was insignificant, since the slopes of expansivity on heating and cooling in this temperature range were nearly identical. At the transformation temperature, however, because of the spontaneous rearrangement of atoms the facility for sintering appears to be greatly increased.

B. W. GONSER*—The authors did a very fine job, and everything is very much in order for the work that was covered.

My discussion is a little broader than the subject covered by the paper, but it is activated by noting the purity or type of titanium used. This whole subject of titanium purity is becoming very involved because of the difficulty of defining the metal which is used as the base for many fundamental investigations.

The Bureau of Mines powder, of course,

is not nearly as pure as that produced by iodide refining. Likewise, even iodide titanium varies quite widely in analysis. As measured by hardness, for example, it may go all the way from a Vickers hardness of 60 to 115. Therefore one should define very closely the base material used to give an indication of what the properties are going to be. This is involved because of the difficulty of determining many constituents. Particularly the non-metallics, as oxygen, nitrogen, or carbon, are difficult to determine, and yet are very profound in their effects.

I think if more fundamental work is done on titanium it should be done with very well defined iodide titanium, or even purer metal if there is a better method of making it, to get consistent results on a reasonably sound base.

This choice of base material is important because so much is being done with titanium on different bases and results can be confusing. A lot of work is probably going to have to be done over again from time to time with titanium of improved purity.

J. T. MILEK*—Did the authors observe the phenomenon which J. D. Fast and DeBoer, I believe, observed in their experiments with zirconium wire, that is, by impressing a dc current voltage on a zirconium wire one can change the wire from an embrittled wire to a ductile wire? The explanation given by the authors is that the oxide and/or nitride which cause the embrittlement in the wire are transported to one pole—I believe it was the cathode. While the above work was carried out on zirconium, did the authors observe the same phenomenon with the titanium wire?

Communicated: This phenomenon was observed by J. H. DeBoer and J. D. Fast and reported in *Rec. Trav. Chim.*, Vol. 2, pp. 161–167, (1940). DeBoer and Fast reported that as a piece of brittle zirconium containing oxide is placed under a high vacuum and a dc potential of such a magnitude that the wire attains a temperature of approximately 900°C, the oxygen will migrate through the bar and collect at the anode. This migration can be reversed any number of times by changing the polarity of the current. Ductility can be restored through the cathode by such treatment.

While the above phenomenon has been observed in zirconium metal it is not unreasonable to assume that it can occur in titanium metal, or perhaps by a stretch of the imagination, even in titanium alloys. This latter process may find commercial applications.

W. A. JOHNSON†—I find the results given in Fig 3 for the variation of the resistance with temperature rather interest-

ing, since above the transformation temperature the resistivity seems to decrease with rising temperature.

This is a rather uncommon behavior, and I wonder whether possibly the transformation does not occur quite as rapidly as is indicated, and this decrease in resistivity perhaps is simply a gradual transformation with an increasing amount of a lower resistance phase.

W. C. ELLIS—Dr. Gonser brought up the matter of the purity of the metal which was investigated. It was not high purity in the sense of some of our more usual metals, as shown by the analyses in the paper. I agree with Dr. Gonser that it is desirable to carry out fundamental investigations on metals of high purity. However, in view of the increasing commercial importance of titanium and the fact that the methods which produce the high purity titanium are expensive and have produced only small quantities in a lot, we think there is good reason to have data on the properties of magnesium-reduced titanium.

Mr. Milek brought up a very interesting fact. Ionic transport is not only found in impure zirconium, but is of general interest in other alloy systems. We ordinarily think of electrical conduction as electronic in metals, but in some metal systems there is good evidence that there is a transport by one of the ions. Data have been reported on transport of carbon in steels by applying dc voltage.

In answer to Mr. Milek's question, no experiments of this character were made in our work on titanium.

Mr. Johnson discussed the unusual occurrence of a decrease in electrical resistivity with temperature in the high temperature phase of titanium. The authors are also mystified by this, but believe that it is a real effect, and not the result of a slow transformation. On cycling the specimens through the transformation a number of times, the temperature of the transformation as shown by the electrical resistivity data occurred always at the same level.

J. L. WYATT*—In line with this discussion which has been completed, would you mind telling us how long you held your specimens at temperature before taking your measurements above 885°C.

E. S. GREINER—The sample used for the electrical resistance measurements at temperatures above 885°C was maintained at the respective temperatures for 15 to 30 min. Stabilized conditions for the measurement at the respective temperatures were established by the obtaining of essentially constant values of the resistance in two successive determinations.

Property Changes during Aging

By A. H. GEISLER Junior Member AIME

DISCUSSION

(P. R. Kosting and W. A. Johnson
presiding)

P. MELARA*—Dr. Geisler, would you say that the physical properties of tensile, yield, and ductility for an aluminum alloy aged at room temperature are comparable to the physical properties obtained by the aging at elevated temperature of the same alloy? I would consider the aging at room temperature to be for an indefinite period of time, for example, ten, twenty, or even fifty years.

A. H. GEISLER (author's reply)—I think that the properties which could ultimately be obtained by aging at room temperature can be predicted from those developed by aging at elevated temperatures. Although 50 years is probably not long enough for the strength of an alloy like 24S to attain that provided by aging at elevated temperature, eventually the strength on aging at room temperature should be greater. If a finite rate of precipitation obtains, I see no reason why room temperature should be any exception from the conventional behavior that the maximum strength or hardness and the time to attain it both increase with decreasing temperature of isothermal aging. Care must be exercised, however, to compare analogous portions of the aging curves; changes during the first few days of aging at room temperature may correspond to the initial hardness peak (as in the case of 24S alloy) whereas the main portion of the curve for elevated temperature aging corresponds to the second hardness peak.

J. B. HESS†—My comment involves a minor, and probably obvious point in connection with Dr. Geisler's description of the mechanism of "discontinuous precipitation," which he calls the "grain boundary reaction." According to the present viewpoint, this reaction is fundamentally recrystallization, with complete decomposition of the matrix accompanying the recrystallization. The author suggests that this recrystallization results from plastic strains produced by prior precipitation at the grain boundary areas.

A characteristic feature of the aging of magnesium base alloys is the onset of the grain boundary reaction at a very early stage of the process. In fact, metallographic and electron microscopic studies tempt one to believe that grain boundary precipitation in these alloys is of the pearlitic form, and therefore typically of the recrystallization type, from the very

start. Based upon the hypothesis of prior precipitation, it is also difficult to rationalize the fact that the recrystallization reaction frequently proceeds from the grain boundary into only one of the adjoining grains.

Fortunately another source of the strains to initiate recrystallization suggests itself. Thermal contraction is anisotropic in magnesium, so that in polycrystalline samples this property should produce strains during cooling from the solution heat treatment, identical in character to those reported to produce fatigue by thermal cycles in tin, cadmium, and zinc. While no evidence of thermal fatigue in magnesium has been reported, so that the severity of such strains in magnesium are probably less, still I have been able to demonstrate their existence by use of Barrett's X ray microscopy technique.

The grain boundary reaction has also been reported to be almost the exclusive type of precipitation in tin alloys containing bismuth (J. E. Burke and C. W. Mason: *Trans. AIME* (1942) 147, 300) where thermal contraction strains should be more severe.

Accordingly, the mechanism of "discontinuous precipitation" should probably be generalized to include recrystallization resulting from strains other than those of prior precipitation.

A. H. GEISLER—Perhaps the precipitation strains are not always responsible for the recrystallization reaction but quenching strains in anisotropic metals may sometimes contribute. On the other hand, these could hardly account for the reaction frequently observed with alloys of the isotropic metals Al, Cu, and Fe. In addition, I do not think that the existing data are sufficient to conclude that the recrystallization reaction can progress in the absence of general precipitation in any alloy system.

I appreciate the usefulness of the electron microscope in extending the resolution of precipitates but some of the existing replica techniques do not permit full utilization of this increased resolution. I would not conclude that general precipitation was absent without consulting X ray patterns of single crystals. While a minimum quantity in excess of a few percent by volume must be present in order to detect the precipitate by X ray diffraction, the restricting particle size may be well below that for electron microscopy as currently applied to metals.

A slight misstatement of my conclusions regarding the recrystallization reaction should probably be clarified. This process is presumed to result from plastic strains produced by precipitation throughout the grains, not at the grain

boundaries alone. It is nucleated at grain boundaries not because of preferential precipitation here but because the activation energy is lower much as in the cases of localized precipitation and the decomposition of austenite into pearlite. I see no difficulty in rationalizing the morphology of the recrystallized nodules; it is identical with that of pearlite. Growth into only one of two adjoining grains suggests a favored orientation relationship between the distorted matrix and the recrystallized matrix analogous to a recrystallization texture.

F. C. HULL*—One of the previous discussers asked whether long time aging at room temperature would be comparable to a shorter period at an elevated temperature. I believe the results as judged from physical property tests might be very similar, but that if one could count the number and size of "coherent" regions and precipitated particles, a difference would be found. In the case of the isothermal transformation of austenite to pearlite at subcritical temperatures, it has been found that the rate of nucleation increases more rapidly with undercooling than the rate of growth.† At low transformation temperatures, therefore, the austenite reacts to form a larger number of smaller pearlite nodules. Nucleation and growth in age hardening systems might behave in a similar manner.

A. H. GEISLER—It is generally agreed that the rate of growth of the precipitate as controlled by rate of diffusion decreases with aging temperature whereas the rate of nucleation as controlled by both the rate of diffusion and degree of undercool goes through a maximum with decreasing temperature of isothermal precipitation. Thus, complete precipitation results in more numerous but smaller particles at the lower aging temperature, a condition which has been assumed to be responsible for the greater ultimate hardness and strength.

W. A. MUDGE‡—I do not think we should allow the chairman to close this meeting without an expression of gratitude for the excellent work which has been done in this case by Dr. Geisler. It is only through such careful work as this that we may hope to understand eventually what happens in the complicated commercial age-hardening alloys, particularly those of high melting point, such as the nickel-base material, where age hardening is accomplished by two or

‡ International Nickel Co.

three elements. I hope that Dr. Geisler and his associates will at some future time have an opportunity to study these more complicated systems.

A. H. GEISLER—While studies of the mechanism of precipitation have been confined in the past to binary alloys for simplicity, they are now being extended to multi-component alloys. The first step has been considered alloys in which only one phase precipitates but eventually it will be desirable to study alloys in which two or more phases can precipitate simultaneously.

R. A. RANDEBAUGH*—It has been suggested by Bain that quench hardening might be considered a special case of age hardening, the properties as quenched being compared to the maximum properties in age hardening alloys, quenched and subsequently aged to develop optimum precipitated particle size.

I wonder if the author has given any consideration to the application of his theories to quench hardenable alloys?

A. H. GEISLER—Yes, the concept of coherency and the characteristics associated with this state have been considered for other reactions in solid solutions. The work in progress is concerned with superlattice formation but the eutectoid reaction will be investigated also. Current consideration of the martensite reaction as a nucleation and growth process and recognition of the product as a coherent transition lattice will facilitate the analogy.

A. GUINIER†—It is obvious that in

the regions where the concentration of foreign atoms becomes abnormally high, the matrix lattice is more or less disturbed.

On the other hand, the evidence indicates in many cases that it is not possible to describe the structure of these zones as the structure of the precipitate with slight changes due to the size of the nucleus and the coherency with the matrix lattice.

For instance, in Al-Cu alloys,³⁹ the streaks, visible on the X ray patterns (with monochromatic rays) in the early stages of aging, split, in a further stage, into diffuse spots definitely different from the spots of the θ' precipitate. That means that the structure of the "G.P. zones" cannot be considered as an imperfect θ' structure.

In Al-Ag or Al-Zn⁴⁰ alloys, the beginning of the aging is characterized by the fact that each node and also the center of the reciprocal lattice is surrounded by the same scattering zone which has the shape of a spherical shell. Such a diffraction effect is quite different from the one- or two-dimensional diffraction effects quoted by Dr. Geisler. This effect cannot be explained on the basis of the structure of the precipitate (Zn or Al-Ag₂); but it is very easily accounted for by the hypothesis of nuclei enriched in solute atoms and keeping without great change the structure of the matrix lattice.

Recent reports show that the zones of gathering of the solute atoms are by no means always plate-like, but that they also can be nearly spherical.⁴¹

A. H. GEISLER—The discussion so kindly submitted by Dr. Guinier is concerned with the interpretation of diffuse X ray diffraction effects, a subject that

was not discussed in the present paper but was considered in detail in Ref 77. Unfortunately, the latter was not yet in print when the present paper appeared. I entirely agree that the diffraction effects do not always suggest plate-like particles but change gradually as one, then two and finally three dimensions of the particle become adequate for sharp diffraction through normal growth at anisotropic rates. On the other hand, the evidence mentioned for Al-Cu alloys is no criterion for concluding that the structure causing the diffuse diffraction effects is different from the θ' structure. Results for an Al-Mg-Si alloy described in Ref 7 show that while spots in patterns for thin platelets do not coincide with those for large particles of precipitate, the configurations in reciprocal space determined by the analysis of not one but of many patterns are intimately related. In this case there is no question that the diffuse diffraction effects originate in a structure similar to that of the thick precipitate particles rather than the matrix. A possible explanation of the spherical zone of diffraction about matrix nodes of Al-Ag and Al-Zn alloys based upon structure of the precipitate is discussed in the cited reference.

Factors Affecting the Tensile Notch Sensitivity of Magnesium Alloy Extrusions

By I. CORNET, Member AIME

DISCUSSION

(P. R. Kostling and W. A. Johnson
presiding)

J. C. McDONALD*—The type of work presented here by Professor Cornet had its origin in field observations which

seemed to indicate that magnesium was more notch sensitive than aluminum. As it was shown in our previous ASTM paper¹¹ and as confirmed by Professor Cornet's results, the static notch sensi-

tivity of wrought magnesium is similar to that of wrought aluminum. As shown in our ASTM paper, the field observations noted above were actually a consequence of the greater toughness of the high strength wrought aluminum alloys compared to the wrought magnesium alloys.

Effect of Grain Size on Tensile Strength, Elongation, and Endurance Limit of Deep Drawing Brass

By H. L. WALKER, Member AIME, and W. J. CRAIG

DISCUSSION

(A. I. Blank and E. W. Palmer presiding)

A. I. BLANK*—This paper is a valuable addition to the published data on the effect of grain size on endurance properties of deep drawing brass sheet. Previous investigators^{7,8} of annealed wrought copper alloys have dealt mainly with the commercial ranges of grain size, and it is interesting to note that the data presented in this paper for commercial grain sizes closely confirm the earlier findings. This is probably the first time, however, that endurance properties for deep drawing brass of less than 0.010 mm grain size have been reported. Full advantage should be taken of the high endurance strength which is associated with these very small grain sizes.

As the authors have pointed out briefly, however, such grain sizes provide less ductility for forming purposes and, in addition, it will be appreciated that very small grain sizes are not too readily obtained in ordinary commercial practice. Special processing schedules and precise control of even nominal impurity content would normally be required to produce such grain sizes consistently and without the danger of incomplete recrystallization. These limitations are not intended, however, to detract from the merit of the authors' contribution.

H. L. WALKER (authors' reply)—The specimens upon which this work was conducted are from normal commercial production. The mill does not find it to be such a difficult task to control the grain size rather closely and the specifications call for a rather small variation in grain size. I should say the smaller grain sizes can be controlled within ± 0.002 mm diam. It is important to know the effects of ready-to-finish grain size and the amount of final cold reduction, and especially the latter. We have not encountered difficulties in securing complete recrystallization during the final anneal. The times and temperature of annealing are such that coalescence does not readily take place, which gives considerable flexibility in the annealing schedule. I should again like to point out that brass with the grain sizes reported here is being produced commercially.

L. W. GLEEKMAN†—I trust Professor Walker will not find me overbearing when I bring up a topic he said was not

going to be developed in this paper. That was with regard to the effect of grain size on tensile strength and grain size.

I notice your Fig 3 does not go beyond the value of grain size of 0.024 mm diam. I was curious as to whether the curve of elongation vs. grain size would show a maximum elongation at an intermediate grain size. My reason for this is that work I did on a 14-carat gold alloy showed that the elongation rose to a maximum at a grain size of 0.025 mm and then fell off rather appreciably at higher grain sizes. I recall that Jeffries and Archer⁹ and also D. K. Crampton,¹⁰ showed similar results for elongation versus grain size.

I wonder if elongations for the two larger grain sizes were reported, would you get that maximum and subsequent decrease?

H. L. WALKER—Professor Gleekman is not overbearing in asking the question. We felt that the larger grain sizes with respect to tensile strength and elongation had already been reported in the literature a number of times. I should expect the elongation to reach a maximum value and then decrease with very large grain size. The tensile strength would not however reach a minimum value and then increase with increased grain size.

E. W. PALMER*—I have a couple of points that I would like to bring up. One of them is concerned with the fact that starting with an initially small grain size and giving fairly heavy reductions is a very fine way to develop directionality in a material. I am wondering if Professor Walker cares to comment on what influence directionality might have had on his work, especially with respect to the direction of test of a fatigue specimen.

There is another point. In explanation of some of the annealing curves, there is some discussion of a recovery period. If this starting material were stress relief annealed to start with, I am puzzled as to what you mean by "recovery period," in Fig 1.

H. L. WALKER—With respect to the production of directionality I wish to comment that we believe the rolling schedule affects the production of directionality. In the paper as originally written the rolling schedule was specified, but the reviewers declared it to be unimportant and it was deleted from the manuscript. The rolling schedule does affect directionality and stresses. We have found that some alloys prone to fire

cracking during annealing may have the tendency to fire crack mitigated with proper adjustment of the rolling schedule. The diffraction patterns after recrystallization, and the tensile strength at 45 and 90° to the direction of rolling did not indicate any marked degree towards directional properties.

As to recovery, I consider recrystallization phenomena cover three distinct processes, the first called recovery, the second called recrystallization, and the third called coalescence.

Recovery I take to mean when in the X ray diffraction pattern there is a sharpening of the lines without appearance of any other visual changes. In other words, I believe there is a bringing together of the atoms into positions which give much sharper lines. Some may call this the incubation period for recrystallization. There may be the establishment of nuclei, but if so, they are not apparent from a diffraction pattern nor are they visible under the microscope.

The second process, recrystallization itself, I would define as the production of strain free grains through nucleation and growth, and strain free grains growing at the expense of strained grains for the establishment of an essentially strain free structure.

The third process, coalescence, is the growth of strain free grains at the expense of other strain free grains, and probably the driving force, or the energy exchange, is surface energy.

E. W. PALMER—With regard to recovery, would not that process of relief of strain on an atomic scale have occurred already in the strain relief anneal given to the material with which you started?

H. L. WALKER—Certainly some would have taken place. There is no question about that. But it does not necessarily indicate that it was complete, because I believe that recovery did take place in the series of anneals shown in Fig 1.

A Copper-base Alloy Containing Iron as a High-strength High-conductivity Wire Material

By W. HODGE, R. I. JAFFEE, Junior Member AIME, J. G. DUNLEAVY and H. R. OGDEN

DISCUSSION

(A. I. Blank and E. W. Palmer presiding)

P. G. MAGANUS*—The type of work we do is in the resistance welding field, and we are wondering if this particular alloy might not be satisfactory in the making of these particular machines we have in mind. We would like to know what the magnetic properties of this par-

* Progressive Welder Co.

ticular alloy are. In other words, if put in the field on current, we would like to know whether or not it would heat up.

W. HODGE (authors' reply)—I cannot give a definite answer to your question. The alloy we know is ferromagnetic. As to applying it to the application about which you have asked, we have done no experimental work along that line.

L. PESSEL*—What are the fatigue

* Radio Corporation of America.

properties of the alloy?

W. HODGE—We have actually made no fatigue tests on the alloy.

P. G. MAGANUS—I thought about melting and casting. I also happen to be a foundryman. I was wondering what this "Riser-X" was. The authors have it in quotes. Is that an iron base? I would imagine so, since it is exothermic.

H. R. OGDEN (authors' reply)—Yes, it is.

A High Strength-High Conductivity Copper-silver Alloy Wire

By W. HODGE, R. I. JAFFEE, Junior Member, J. G. DUNLEAVY and H. R. OGDEN, Junior Member AIME

DISCUSSION

(A. I. Blank and E. W. Palmer presiding)

W. HODGE—Since this paper was written the Signal Corps has sponsored the commercial development of this alloy. Work was carried out by the American Brass Co. under the able direction of R. D. Hull, and we are quite certain now that it is possible to produce an alloy of 6½ pct silver which will have high strength and high conductivity.

M. G. CORSON*—I am not in the habit of congratulating authors and I am quite sure they are in no need of congratulations, but I am glad that due to their efforts silver might become far more useful technically than it is today.

The characteristics of Cu-Ag alloys intrigued me long ago and it is now more than ten years since I broached the subject to the late W. H. Bassett of the American Brass Co. I did not experiment to such a great extent as the present authors did, nor did I get highly precise and uniform results. I saw, however, that with as little as 3 pct silver one might have copper conductor wire with over 100,000 psi strength and a conductivity of 90 pct. Besides, such wire is immune to permanent softening when exposed to a temperature up to 450°C.

Mr. Bassett could not see my suggestion from the commercial viewpoint, for obviously a wire with 3 pct silver would cost at least double the price of ordinary

copper. It is a fact that OFHC copper in spite of all its advantages has hard sledding because its price is about one cent higher per pound. This cost question will form an enormous stumbling block in the way of Cu-Ag alloys, but I hope the future belongs to it.

By the way, I also suggested such uses of copper to the Mexican government, for that country could produce far more silver if there were a demand for it. My suggestion was not even honored with a reply. It is ridiculous that silver cannot have a definite price because it is obtained mostly as a byproduct, and the price of silver depends upon the arbitrarily fixed value of residues from copper, lead and zinc production. If we were not still under the spell of the idea that silver is a precious metal of an inherently high price, the latter might (and should) drop enormously and silver would become just a technical metal; that is where it belongs.

Regarding the degassing of Cu-Ag alloys I should suggest to the authors that they try blowing into the molten alloy first a stream of carbon monoxide in order to eliminate oxides and oxygen, then a stream of dry, oxygen-free nitrogen to remove whatever CO is retained. I found the method to work well in a number of cases.

P. J. MAGANUS*—I am in full agreement with Mr. Corson on the fact that these alloys are rather expensive, because

we have worked with these alloys, too, in an experimental foundry that we have. If it were not for the fact that the stuff costs around 80 cents a pound, we probably could use it also in the resistance welding field.

One of the questions that I have is the fact that, in our foundry, when we used magnesium as a deoxidizer it also acted as a hardener all right, but it has the effect of absorbing gases or at least we get a lot of porosity when we have magnesium. When we forget to add magnesium and add other deoxidizers such as lithium or calcium borate or some of the other deoxidizers that work pretty well, we do not have that trouble. Can the author give us an idea?

In Fig 1 he gives the conductivity of these various elements and how much they depress the copper. I was wondering what magnesium does. In other words, I know that in the work we have done magnesium can knock down our conductivity to around 80 to 85 pct of copper, and with this conductivity we feel that we should not use it. Has the author some information on that?

W. HODGE (authors' reply)—The point you brought up, of porosity caused by magnesium, is very pertinent. In the laboratory we did not have trouble from porosity caused by magnesium, presumably because of the small melt.

When we attempted to cast larger ingots for cold rolling, the porosity caused by magnesium ruined our entire first

* Consulting Engineer, New York City.

* Progressive Welder Co.

attempt, and Mr. Hull, of the American Brass Co., finally decided to throw some borax on top of the melt, and by so doing he was able to get rid of most of the porosity caused by magnesium. Otherwise we could not have cast the alloy in the air at all. It would have had to be cast quite in a protected atmosphere.

On the other point on conductivity, I could only refer you to a rather old article by M. G. Corson, in which he de-

scribed the effect of magnesium copper alloys. I think it was written in about 1930 and occurs in the *AIME Transactions*.

E. W. PALMER*—I should like to congratulate the authors on the very fine development work that has resulted in these two new high-strength high-conductivity alloys.

The situation in copper-silver and copper-iron was gone over carefully years

* American Brass Co.

ago, looking for precipitation hardening effects. When no hardening was discovered, the systems were dropped.

The discovery by Mr. Hodge and his co-workers, that these precipitation hardened matrices have enormously high rates of work hardening that permit them to be drawn to very high strength is of fundamental importance, and the authors deserve a great deal of credit for this development.

The Effect of Chromium on the M_s Point

By J. B. BASSETT and E. S. ROWLAND, Junior Member AIME

DISCUSSION

(C. S. Smith and A. R. Troiano presiding)

A. E. NEHRENBURG*—From the practical viewpoint it is not particularly important whether 1 pct chromium lowers the M_s temperature of steels containing 1 pct carbon 65°F as indicated by the data just presented, or about 40°F as shown by Klier and Troiano.² This is because such high carbon steels are not austenitized commercially at a high enough temperature to dissolve all of the carbides present. In such cases the actual M_s temperature is considerably higher than one would predict on the basis of the known effects of the alloying elements present. However, it is somewhat disturbing that there should be this disagreement among these investigators. Perhaps a few comments on this discrepancy would be in order.

It seems to this discussor, in spite of the arguments of the authors to the contrary, that the possibility exists that the time allowed for the hot oil quench used for temperatures below 350°F may not have been long enough to permit the specimens to reach the bath temperature before they were tempered. It may be significant that in the authors' Fig 6 which shows the relation between the M_s point and chromium content for the two carbon levels studied, the five points which do not agree with published data all were obtained using hot oil for the initial quench. For the compositions which have M_s temperatures high enough so that molten salt could be used for their determination, there is good agreement with published data, even at the 1 pct carbon level. It is recognized, however, that there is one point based on a hot oil quench which does not deviate from the expected value.

In their paper Klier and Troiano² indicated that steps were taken to establish that the temperatures of the quenching baths used were attained. There is no indication that this was done in the investigation just described. Therefore this discussor is inclined to agree with Klier and Troiano that 1 pct chromium lowers the M_s temperature of steels no more than about 40°F irrespective of variations in carbon from about 0.40 to 1.3 pct.

It is of interest to compare the M_s points reported in the present paper with calculated values. Formulas which have been proposed for calculating M_s temperatures contain factors for carbon which vary from 540 to 650.^{1,8,9} The significance of this variation in the carbon factor can be established if common factors are assigned for each of the alloying elements in these formulas other than carbon.

The M_s temperatures shown in Table 6 were calculated by using the Grange-Stewart and the modified Payson-Savage formulas with common factors of 70 and 40 for Mn and Cr, respectively. The effect of the residual Si and Ni was neglected.

It will be noted that when the carbon content is about 0.50 pct the difference in the carbon factor used in these formulas has no effect on the accuracy of the calculated M_s temperature, and that there is good agreement with the measured values. The maximum deviation is only 20°F. When the formula containing the higher carbon factor is used 9 of the 12 steels have calculated M_s points which differ by only 10°F or less from the measured values. When the formula containing the lower carbon factor is used the calculated M_s temperatures of 10 of the 12 steels differ by no more than 10°F from the measured values.

At the 1.0 pct carbon level, however, calculations based on the formula having the higher carbon factor tend to be con-

siderably lower than those based on the one with the lower carbon factor, as the table indicates, and do not agree as well with the measured values.

Earlier in this discussion it was suggested that the M_s temperatures shown for the five higher chromium steels might be low. If that is so, there would be even better agreement between calculated and measured M_s points for the modified Payson-Savage formula than the table indicates and a greater deviation for the Grange-Stewart formula. Be that as it may, the results as they stand indicate that the modified Payson-Savage which contains the lower carbon factor appears to be more satisfactory at this high carbon level. Additional data which confirm this fact were presented in my discussion of the Grange-Stewart paper.

The carbon factor used in the Grange-Stewart formula is based on data published by Greninger¹⁰ and by Digges¹¹ which showed that 1 pct carbon in pure iron-carbon alloys lowers the M_s temperature 650°F. The carbon factor in the modified Payson-Savage formula was also based on data published by Greninger¹⁰ which showed that 1 pct carbon in commercial iron-carbon alloys corrected to 0 pct Mn lowers the M_s temperature 540°F. Since these differences in the carbon factor were reported by a single investigator it seems reasonable to conclude that the impurities present in carbon steels have an effect on the rate of lowering of the M_s temperature with increasing carbon.

Grange and Stewart in the closure to their paper¹ also presented data to show the effect of variations in carbon on the M_s temperature of carbon steels. These data and those of Greninger, corrected to 0 pct Mn, are plotted in Fig 7. There is good agreement among these investigators. Grange and Stewart not only confirm that 1 pct carbon lowers the M_s temperature of commercial steel 540°F, but

* Crucible Steel Co. of America.

² References are at the end of the discussion.

also show that the effect of carbon is not linear above about 1 pct. The rate of lowering of the *Ms* temperature with increasing carbon above 1 pct gradually decreases so that a correction based on Fig 7 must be made if the *Ms* temperature for a steel containing more than this amount of carbon is to be calculated.

It cannot be emphasized too strongly that *Ms* temperatures can be calculated only when the austenitizing temperature is sufficiently high so that there are no residual carbides present. Since this generally occurs commercially in only the medium carbon steels where either of the formulas discussed above is equally accurate, it usually makes little difference whether one or the other is used for the calculation of the *Ms* temperature. However, it should be remembered that the effect of carbon in commercial steels is somewhat less than the Grange-Stewart formula implies.

If it is desired to calculate the *Ms* temperatures of steels containing 1 pct carbon only the modified Payson-Savage formula can be used to obtain values which will be reasonably accurate.

The authors conclude that "as far as steels containing chromium are concerned, no simple formula is adequate for the accurate calculation of *Ms* points." This is contradicted by the fact that there is reasonable agreement with the authors' own data when the *Ms* temperatures are calculated using the modified Payson-Savage formula. Furthermore, data presented in my discussion of the Grange-Stewart paper showed that the agreement between calculated and measured *Ms* temperatures was remarkably good for the chromium steels 5140 and 52100 and for the 1 pct carbon steels containing from 1 to 9 pct chromium studied by Klier and Troiano.

FIG 7—Effect of carbon on *Ms* temperature of carbon steels. Variations of carbon in plain carbon steels between about 0.2 and 1 pct lower the *Ms* temperature at the rate of 540°F per 1 pct carbon.

A. R. TROIANO*—There seems to be some question about the disagreement in the rate of lowering of *Ms* with chromium in the high carbon steels. Did the authors make any grain size determinations, or could they tell us approximately what the grain size was? In the work that Dr. Klier and I did, we had exceptionally large grains, and since we now know that the grain size may change *Ms* by as much as 35°C, it is possible that the disagreement may be caused by this phenomenon.

* University of Notre Dame.

If the authors had a smaller grain size, the deviation would be in the right direction.

E. S. ROWLAND (authors' reply)—The authors are indebted to the discussers of this paper for their comments and criticisms.

First, in answer to Mr. Nehrenberg, we fear that he missed the implication contained in the opening paragraph of the paper in regard to the effect of small variations in chromium content on the *Ms* temperature. The curve of Fig 11 of the Grange and Stewart¹ paper indicates that the effect of chromium on *Ms* might be very much greater than previously anticipated in the range of chromium contents normally expected to be in solution in the austenite of SAE 52100 at its commercial austenitizing temperature (about 1550°F). It was conceived possible that small variations in austenitizing conditions might produce a significant shift in the martensite temperature range if the above curve expressed the true relationship. Mr. Nehrenberg is right in stating that the difference between 40 and 65°F per 1 pct chromium is unimportant but an effect two or three times either of these values at low chromium contents would have been important. As it turned out, the relationship between chromium and *Ms* temperature is undoubtedly linear and this effectively disposes of any such arguments.

Mr. Nehrenberg's second criticism is much more serious since it throws doubt upon the validity of all the data obtained by questioning the fact that the specimens actually reached the quenching bath temperature. In the first place, the

Table 6 . . . Effect of Carbon Factor on Calculated *Ms* Temperatures

| Steel | C | Mn | Si | Ni | Cr | Measured <i>Ms</i> , °F | Calculated <i>Ms</i> | | Deviation | |

(a) *Ms* (°F) = 930 - 540 C - 70 Mn - 40 Cr (Based on Payson-Savage Formula)

(b) *Ms* (°F) = 1000 - 650 C - 70 Mn - 40 Cr (Based on Grange-Stewart Formula)

specimens used were rough cut to the sizes indicated in the text but by the time they were cleaned up by hand grinding, the actual sizes were about $\frac{3}{32}$ in. square and $\frac{5}{32}$ in. square, respectively. Nevertheless, actual cooling times were obtained on $\frac{1}{8} \times \frac{1}{8} \times \frac{1}{2}$ in. long specimens, after austenitizing at 1800°F, during a salt quench at 350°F. This work was done by welding 24 ga thermocouples to each of two specimens and connecting them to two channels of a Hathaway 12 channel recording oscillograph. The strings had a dc sensitivity of 55 mm per mil amp at 1 meter distance and a natural frequency of 400 cycles per sec. The results showed that both specimens were within 10°F (about the experimental error of the determination) of the bath temperature in 4 sec.

At several times during the investigation, the smaller specimens were checked against the larger, using the austenitizing conditions and quenching times in both salt and oil described for the high carbon steels. In all cases the results were identical. Furthermore, both oil and salt were used interchangeably in the range of 300 to 350°F with the same results on many check runs. Finally, duplicate specimens quenched together using the oscillograph produced differences in temperature of 25°F when only 50°F above the bath temperature and separate runs showed even greater deviations. It is believed that these data support the contention that reproducibility of results is a satis-

factory indication that the specimens have actually reached the quenching bath temperature. So many variables enter into the actual quenching operation that reproducibility is out of the question if the specimen is removed from the bath while still above the bath temperature.

Mr. Nehrenberg also criticizes our statement that no simple formula will suffice to express the relationship between the effects of carbon and chromium on the *Ms* temperature and in defense of his objection shows that the modified Payson-Savage formula will predict the *Ms* points within 25°F. Our statement was based on the fact that the effects of carbon and chromium on the *Ms* points of these steels are interdependent and not independent as formulas of the Payson-Savage and Grange-Stewart type assume. Either or both may arrive at a reasonable prediction by a series of compensating errors, but a more complex formula would obviously be required to express accurately the true relationship between carbon and chromium in this regard.

In answer to Dr. Troiano's question regarding the grain size of the specimens after the austenitizing treatment, samples of 1.5 pct chromium steel were heated for 20 min. at 2100°F and isothermally transformed at 1300°F for 3 min. to delineate the grain size. The resulting ASTM grain size was No. 2. We are unable to assess this result in terms of Dr. Troiano's statement of "exceptionally large grains" obtained in his work.

Since the manuscript for this paper was submitted, both Dr. Troiano and Dr. Cohen have shown an effect of grain size on *Ms*. Since high austenitizing temperatures are necessary for the complete solution of high carbon chromium steels, coarse grain size is unavoidable and its effect on *Ms* difficult to separate from carbide solution since both are changing simultaneously. Our only pertinent observation in this regard was that with increasing austenitizing temperature, the *Ms* became constant shortly after the complete disappearance of carbide in the quenched microstructure and did not change upon a further increase of austenitizing temperature of 100°F.

The Kappa Eutectoid Transformation in the Copper-silicon System

By W. R. HIBBARD, JR., Junior Member, G. H. EICHELMAN, JR., Student Associate AIME, and W. P. SAUNDERS

DISCUSSION

(C. S. Smith and A. R. Troiano presiding)

C. S. SMITH*—The authors refer to some earlier work of mine containing reference to the pearlitic structure of these alloys. It should, perhaps, be pointed out that the two-phase structure most reminiscent of pearlite is formed when gamma precipitates from super-saturated alpha phase or from an alpha-kappa mixture rich in alpha. This is not a eutectoid decomposition involving three different phases, but is a case of discontinuous precipitation involving two phases (one, however, possibly of two different compositions). It seems not unlikely that a typical nearly-parallel-plate form of pearlite occurs only when there

are three interfaces of approximately equal energy meeting at the advancing boundary of the transformed alloy. When alpha forms from kappa in an oriented manner, the resulting interface is of extremely low energy and the gamma phase can co-precipitate with alpha without the constraint of the third interface.

C. S. BARRETT*—Dr. Smith recently gave me a set of samples of copper-silicon alloys that I have been X raying after different heat treatments. The investigation is not yet completed, but it is already clear that the decomposition of a sample of homogeneous kappa into alpha plus gamma on cooling below the eutectoid temperature is crystallographically very different from the precipitation of

alpha from kappa on heating above 600°C. The diffraction patterns in the two cases are as strikingly different as the appearance of the microstructures, and in the way one might expect from the microstructures: there are normal reciprocal lattice points for all phases after the eutectoid transformation, but after the precipitation, which produces the remarkable striations in the microstructure that Dr. Smith has reported,⁵ reciprocal lattice points are often seen that are greatly elongated. Elongated points are found after only one minute at a precipitation temperature of 750°C but none is found after times up to 45 hr at 500°C.

A. R. TROIANO*—Dr. Barrett has

* University of Chicago.

* University of Chicago.

* University of Notre Dame.

raised an interesting point. Care must be taken in generalizing the term "pearlite" if one is going to draw the analogy with steel. One may have very pearlitic-looking microstructures that do not originate from the eutectoid decomposition of the parent phase.

W. R. HIBBARD, JR. (authors' reply)
—Dr. Smith has emphasized a point which

the authors failed to realize, perhaps because it is somewhat difficult to understand how kappa, even in an alpha-kappa structure, can decompose to plate-like alpha and gamma without involving the eutectoid transformation (see Fig 20 of Ref. 5).

Dr. Troiano's caution regarding the use of the term "pearlite" is most timely.

The striated structure of alpha and kappa formed above 600°C from kappa described by Dr. Barrett obviously is not a eutectoid structure, since gamma is not involved, and it probably looks more "twin"-like than "pearlite"-like, anyway.

Stabilization of the Austenite-martensite Transformation

By W. J. HARRIS, JR., Junior Member, and M. COHEN, Member AIME

DISCUSSION

(C. S. Smith and A. R. Troiano presiding)

A. R. TROIANO*—This paper is full of new observations.

It is very interesting to me to see that now we can rationalize why in some cases one may observe stabilization without any decomposition at all. I distinctly remember how in the laboratories at Notre Dame we found this phenomenon and then tried to check it in other steels and it did not seem to be there. We were beginning to wonder if the original determinations were valid. Now we can see good reasons why it was not observed in all steels.

I wonder if the authors would care to state just how general the relationship between σ_s and M_s might be.

C. S. BARRETT†—Our investigation of the transformation in lithium and lithium-magnesium alloys, which is somewhat like the martensite transformation in steels,¹⁴ is continuing. We are using an improved X ray diffraction unit that has been built by D. F. Clifton to see whether there is stabilization of the high temperature phase on cooling, and to investigate further a behavior that looked like stabilization of the low temperature form during reversion to the high temperature form on heating. Detailed information of this kind for the lithium transformation should be quite helpful in arriving at sound theories of stabilization.

B. S. LEMENT‡—I just want to point out that even though stabilization of austenite can result from quenching to and holding at some temperature below σ_s , the extra austenite at room temperature is not stabilized against room temperature transformation. The reason for the apparent contradiction has been pointed out by Dr. Morris Cohen in his Campbell Memorial Lecture. There are

two different mechanisms involved in the transformation of austenite to martensite. On cooling the transformation probably occurs by a process of nucleation and shear; whereas the isothermal transformation at room temperature probably occurs by growth of the existing martensite plates. Any extra austenite that results from stabilization on cooling to room temperature behaves quite similarly to the other retained austenite with regard to isothermal transformation at room temperature. If more austenite is retained, more transformation occurs on aging at room temperature. This phenomenon is of great importance from the standpoint of dimensional stability of tool steels.

L. D. JAFFE*—The authors have certainly done a fine job in clarifying and establishing many points only suggested by previous work. On one matter, however, there seems to be some disagreement. The authors' Eq 1 indicates that for constant percent martensite (P), M_s-T is a constant. In other words, all curves of percent martensite vs. temperature are the same, except for a uniform shift along the temperature axis. This is not in accord with the data of Grange and Stewart,²⁵ obtained by technique similar to that of authors. As the writer has pointed out,²⁶ these data indicate that M_s-T increases as M_s decreases. Can the authors throw any light upon these apparently contradictory findings?

It may be noted that the discrepancy just mentioned does not affect the authors' conclusion that all the (unstabilized) martensite transformation curves conform to a single function, in which M_s is the only metallurgical variable. This same conclusion was, indeed, drawn by the writer in the discussion cited.²⁶

M. COHEN (authors' reply)—The σ_s

relationships that Dr. Troiano has inquired about seem to hold for the following ranges of composition: 0.75 to 1.35 pct carbon, 0–5½ pct nickel, and 0–3 pct chromium. These limits are not definitely fixed and may be extended when future work is done on additional steels. However, considerable deviation may be expected when the composition is changed radically, as in the case of high speed steel.

We agree with Dr. Barrett that his contemplated studies on lithium and lithium-magnesium alloys will have a significant bearing on the theory of stabilization. For example, in working with steels, we are inclined to wonder about the role of carbon in the stabilization process, whereas if true stabilization occurs in a high-purity metal, one may well question the importance of solute elements in the phenomenon.

Mr. Lement is entirely correct in emphasizing that the term stabilization used in this paper refers only to the inhibition of the cooling austenite-martensite transformation. The increment of retained austenite resulting from stabilization is subject to isothermal transformation in the same sense as normal quantity of austenite retained in the absence of stabilization. In fact, this is one of the main reasons for suspecting that the isothermal transformation of austenite to martensite²⁷ may occur, at least in part, by the growth of existing plates, rather than by the formation of new ones as in the cooling transformation.

It is worth repeating here that the σ_s temperatures determined in this paper are all based on holding times of ½ hr. At the moment, the relation between σ_s and holding time is not known. However, regardless of this possible variation, the main trends should persist, with stabilization becoming more pronounced, the larger the amount of martensite present.

Dr. Jaffe rightly points out that discrepancies exist between the martensite transformation curves presented here and those of Grange and Stewart. No positive explanation is available at the

¹⁴ References are at the end of discussion.

moment, although it should be pointed out that the method used by the latter investigators was only semi-quantitative. The form of the transformation curves as given by Eq 1 is identical with the one found by Howard² for carbon contents ranging from 0.75 to 1.35 pct. On the other hand, Grange and Stewart covered a wider range of carbon contents, and their data may indicate trends that are not detectable in a more limited series of compositions. However, according to

our experience, quantitative measurements are quite difficult in the lower carbon steels and may lead to questionable results even when lineal analysis is employed.

Secondary Hardening of Tempered Martensitic Alloy Steel

By W. CRAFTS, Member AIME, and J. L. LAMONT

DISCUSSION

(C. S. Smith and A. R. Troiano presiding)

R. BALLUFFI* and M. COHEN*—

In the tempering research conducted at M.I.T., carbide precipitation from martensite or retained austenite has never been found to produce an expansion. Consequently, the expansion effects of Fig 11 and 12, attributed by the authors to alloy carbide precipitation, are of some concern to us. We have observed such expansions, but have accounted for them on the basis of retained austenite decomposition. The authors have not used this explanation because they assumed that the retained austenite in their samples had been reduced to negligible amounts by previous refrigeration in liquid oxygen.

With the cooperation of the authors, we undertook a critical experiment to settle this issue. The authors kindly sent us four of the alloy steels under consideration, of which we selected the following two for test:

| Designation | Heat | Pct C | Pct Mn | Pct Si | Pct Cr | Pct V |
|-------------|-------|-------|--------|--------|--------|-------|
| Cr | 4-24 | 0.52 | 0.37 | 0.19 | 11.73 | |
| V | 4-257 | 0.48 | 0.54 | 0.12 | | 2.02 |

Two dilatometric specimens of each composition were austenitized at 2300°F (1260°C) for 12 min.† and quenched in oil. One of each was immediately refrigerated in liquid nitrogen. All four specimens were then subjected to dilatometric runs, covering the significant range of 600–1300°F in 2 hr. The results are plotted in Fig 22 in a manner analogous to that of Fig 11.

The expansion effect is definitely smaller for the refrigerated steels than for the as-hardened steels. This clearly suggests

FIG 22—Dilation on heating 0.5 pct carbon, chromium and vanadium steels, after oil quenching from 2300°F and after refrigeration in liquid nitrogen.

that the expansion phenomenon is the result of retained austenite decomposition inasmuch as the refrigerated specimens undoubtedly contain less retained austenite than the as-hardened ones. If the expansion during tempering were caused by carbide precipitation from the martensite, the refrigerated specimens should exhibit at least as much expansion as the as-hardened ones, and probably slightly more because of the martensite increment produced by the cold treatment. It is also worthy of note that the tempering expansion of the refrigerated specimens represents a sizable fraction of the expansion of the as-hardened specimens. This means that the cold treatment does not convert anything like all of the retained austenite.

These findings should not reflect upon the authors' conclusions as to the cause of secondary hardening in the 0.50 pct carbon steels under study here. While the retained austenite decomposition should not be ignored, we quite agree that alloy carbide precipitation plays an important role in the secondary hardening observed.

D. J. BLICKWEDE*—I would like to point out to the authors two phenomena which occur during the isolation of carbides from steels that might affect their electron micrographs.

One is that carbon in the matrix does not ionize during electrolysis. Instead it

* Massachusetts Institute of Technology.

† Time at temperature.

* Naval Research Laboratory, Washington, D.C.

either comes down as free amorphous carbon or reacts with hydrogen to form hydrocarbon gases. The presence of free amorphous carbon might affect the electron micrographs.

The second phenomenon occurs in the case of alloy steels, in which particles of the matrix material—that is, the steel itself—remain undissolved and will come down with the carbide precipitate. Thus it is quite likely that pieces of matrix material itself could be the carbide residue and show up in the electron micrographs.

W. CRAFTS (authors' reply)—The examination of isothermally transformed bainite should be very informative. A preliminary survey of bainite specimens has indicated that the carbide structures are exceedingly fine and probably quite complex, so that a good deal of difficulty in experimental technique and interpretation may be anticipated. It is expected however, that electrolytic extraction of the carbides may provide a useful tool for furthering our understanding of the nature of bainite. The carbide of a 3 pct chromium steel in the bainitic condition was found to change on tempering from Fe_3C to Cr_7C_3 in about the same temperature range as steel in the martensitic condition, but the specimens were not examined to determine the appearance of the carbides during the transition. In

view of the apparently complex nature of the carbides in bainite, it might be expected that the transition might not be as simple and straightforward as in tempered martensitic steels.

In reference to the discussion by Robert Balluffi and Morris Cohen it should be noted that the analyses given in their discussion represent the same steels that are shown in Fig 11. By an oversight these specimens were indicated in the text to have come from the same heats as those used for the metallographic investigation. The dilation tests indicate that the larger amount of residual austenite in the unrefrigerated specimens increased the amount of dilation on heating in the 1000–1300°F range. It is also quite probable that the refrigerated specimens contained an amount of residual austenite that was too small to be detected in our tests. However, it is felt that a more positive test should be made before eliminating the possibility that the expansion is in part due to transition of the carbide phase. As is pointed out, the actual amount of retained austenite is too small to affect significantly the conclusions regarding the effect of transition to alloy carbide on the rehardening phenomenon.

In electrolytic extraction, as stated by D. J. Blickweide, a certain amount of car-

bide is decomposed to hydrocarbons and amorphous carbon. The attack occurs largely during electrolytic solution of the metal and, although subsequent solution by the electrolyte has been substantially eliminated, the recovery of carbide is never complete and in slightly tempered specimens may be quite low. Thus, the carbide residue is only a partial representation of the total amount and individual carbide particles may be altered from their original condition. The X ray indications, therefore, may be incomplete, but positive results may be accepted, and the appearance of the carbides parallels the collateral properties sufficiently well to give a credible confirmation that the observed structures are significant. Relatively little difficulty due to undissolved particles of matrix material has been encountered in steels that are free from large amounts of residual austenite and the presence of metallic iron in the residue has been found to be a useful criterion of retained austenite. Undissolved carbides and matrix material are too coarse to present any difficulty in the electron microscope examination. Although electrolytic extraction requires careful experimental technique, it offers a means of examining carbide structures that is much more revealing than methods of examination suitable for solid specimens.

Furnaces for the distillation of nitric acid. (Ercker, 1574.)

The tall tower was filled with charcoal which burned only at the bottom and the hot gases passed through the side chambers to heat the alembics containing vitriol, saltpeter and other materials. Fresh charcoal descended to replace that burned, and the furnace would maintain constant heat for as long as a day without refueling or other attention.

The Effect of High Copper Content on the Operation of a Lead Blast Furnace, and Treatment of the Copper and Lead Produced

A. A. COLLINS,* Member AIME

When we speak of high copper on a lead blast furnace we think in terms of 4 to 5 pct, or any lead charge carrying over 1 pct. Any copper on charge will produce its corresponding troubles such as lead well, extra slag losses, drossing problems, and the working up of the dross.

This is indeed a very interesting subject and one that used to give the old-time lead metallurgists such as Eiler, Hahn and Iles many worries, not so much in the actual operation of the blast furnace but in the working up of the copper. When the American metallurgists commenced with the American rectangular-shaped lead blast furnace in the 1870's and got away from the reverberatories such as were in use in Germany and other parts of the world, they went to greater tonnages, as 80 to 100 tons per day in comparison to the 20 to 30 tons per day in the other processes.

With the greater tonnages along with insufficient settling capacity, the silver losses in some cases were increased. Hence the lead-fall was low, for there were no leady concentrates in those days to assist the metallurgist to gain lead or an absorber for the *precious* metals; and in some cases copper sulphides were added intentionally to the charge to produce a copper matte to lessen the silver losses through the dump slag. The operators in those days thought that where some copper was always present in the lead ores the copper should not enter into the reduced lead and alloy with it. This, by the way, is just the reverse of our present-day practice, when we try to put all of the copper into the blast furnace lead and to remove the same through the drossing kettles. Therefore the furnace was operated to produce a certain amount of matte or artificial sulphides, since, due to the great

affinity of copper for sulphur, any copper present would enter the matte almost completely. Thus, the lead bullion produced was practically free from copper.

The products of the furnace were metallic lead or lead bullion, containing 85 to 95 pct of the lead and about 96 pct of the silver which were in the ore—a lead-copper-iron matte which contained nearly all the copper in the ore and the slag, the waste product.

In the United States, up through the year 1892, we find the small furnace $100 \times 32\frac{1}{2}$ in. with 12 tuyeres, some 6 on each side, plagued with a small amount of poorly roasted sulphides—either from heap or hand roasters that produced matte.

This matte was roasted and if poor in copper was returned for the ore smelting. Otherwise it was smelted either alone or with additions of rich slags or argentiferous copper ores, the products being lead and a highly cupriferous matte, the latter being subsequently worked up for its copper.

The lead metallurgists kept trying and improving on furnace and roasting equipment designs until we find Malvin W. Iles constructing at the old Globe Plant at Denver what came to be the modern furnace. That is, in 1900 he built a furnace of 42 in. width by 140 in. at the tuyeres with a 10 in. bosh and a 16-ft ore column. This type has been more or less standard to the present time, though modified in width and length to meet the demand for large tonnages and improvements in structural details. In 1905 at Cananea, Mexico, Dwight and Lloyd developed

the present down-draft sinter machine that has meant so much in producing a well-processed material for the lead blast furnace.

In 1912 Guy C. Riddell came forth with double roasting at the East Helena Plant of the American Smelting and Refining Co., which removed the "zinc mush plague." Incidentally, with the introduction of double roasting, which most lead plants were forced into after 1924, when lead flotation came into its own, less matte or no matte was produced.

When this stage arrived, the copper was forced into the dross and the casting of lead at the blast furnace lead-wells was stopped. In plants with a fair copper carry 1 pct or better on the blast furnace charge, the lead wells became inoperative once the production of matte stopped. The copper drosses clogged the lead wells and even with bombing, either water or dynamite, the operators could not keep them open. Thus, the lead wells were abandoned in some plants, such as at the El Paso and Chihuahua smelters of the American Smelting and Refining Co., and all lead taken out through the first settlers.

The elimination of sulphur, especially sulphide sulphur, from the blast furnace charge and the nonproduction of matte resulted in a great saving of time, energy and equipment in the recirculation of the copper.

With the copper content in the dross and dross-fall ranging in quantities from a few percent up to 60 pct, such as at El Paso, a drossing problem was created.

As the old-time operators hated dross and buried the same in the shipping bullion, the modern metallurgists from 1925 on decided that with increasing dross-falls they would have to adopt the lead refiner's ideas of drossing kettles with subsequent treatment of the lead with a sulphur addition to have the shipping lead of 0.01

San Francisco Meeting, February 1949.

* Manager, Chihuahua Smelter, Chihuahua, Chih., Mexico.

pct copper content or less.

With the cleaning up of the bullion and thus the copper remaining in the lead smelters, the dross reverberatory was developed at the Selby Plant of the American Smelting and Refining Co. and brought to its present stage of development by Mr. O. P. Chisholm, the former superintendent of the East Helena Smelter.

Since 1925, when the real flotation of lead sulphide commenced, the concentrators have gone in some cases from a 10 to a 64 pct lead in the lead concentrates, and the copper has also increased in the same concentrates, in some cases up to 14 pct. Consequently, the lead smelters have received a considerable amount of copper in these lead concentrates.

These higher copper-lead concentrates along with complex copper, zinc, lead ores after roasting give a high copper charge to the lead blast furnaces, say up to 5 pct, and have in no way retarded the furnace speeds. On the contrary, the furnace tonnages have increased. The copper minerals contained in the original ores and concentrates have been mainly chalcopyrite and chalcocite and have assisted in producing a good, fast-smelting sinter at the blast furnaces. The copper sulphides have retarded the lead fusion and permitted a greater degree of zinc sulphide roasting. Thus, the copper sulphides have aided in sintering.

Therefore, high copper on a lead blast furnace, if in the form of a well roasted sinter, will not cause any trouble in the working of the furnace.

Copper in the form of dross, when added to a lead furnace and necessitating a sulphur addition for matte making, will foul a furnace and cause it to work inefficiently. Any sulphides added raw to matte out the copper in combination with zinc will produce a zinc mush, along with accretions and an irregular working of the blast furnace.

Any copper on the furnace charge with the present-day double roasting will go either to the speiss, lead or slag, the amount depending upon the arsenic on charge, as the speiss and the slag losses will depend upon the quality of the sinter.

The blast furnace speiss production will vary from plant to plant, depending upon local conditions and the amounts of copper and arsenic on the charge. I well remember at the El Paso smelter for the years 1939 through 1944, with an average of about 0.6 pct arsenic on the furnace charge, that no

speiss was produced with over 1.5 pct copper on charge. However, with under 1.5 pct copper we always showed some speiss.

The copper in the blast furnace speiss can be reclaimed through the dross reverberatory, using the iron arsenide in the speiss as a collector for more copper or else the iron speiss can be ball-milled and roasted for arsenic and the resultant calcine worked up in a copper reverberatory or blast furnace.

The copper slag losses were in no way affected by the speiss-fall.

For our present-day roasting program, the degree of roasting can be ascertained by the amount of copper in the slag. I have a rule of thumb that the copper on charge multiplied by 0.16 should give the percent of copper in the furnace slag. Any amounts below this figure indicate excellent roasting.

The furnace lead with a heavy dross-fall will be hotter and cause extra troubles from the dross separating in transfer pots, along with a greater strain in the lead receiving kettles due to heavy accretions formed on sides of the kettles and necessitating more frequent barring down of the same. Frequently at El Paso, with its heavy dross-fall, I have seen a full 65-ton kettle show about 20 tons of lead after the drossing operations. The reduction in no way will affect the quantity of dross produced.

Blast furnace lead containing its copper in the form of dross and varying from a few percent up to, say, 60 pct will be deposited on the surface of the lead in the drossing kettles and will be worked up in either one of three ways, viz: 1. Fluxing with soda ash in the dross reverberatory. 2. Using the arsenic in the blast furnace speiss as the collector of copper in the dross reverberatory. 3. Fluxing with silica and using a sulphide as a collector for the copper.

The copper products from the reverberatory, such as the matte and speiss, can be sent direct to a copper department; or the speisses, especially of soda, can be roasted with an iron diluent for arsenic elimination and the resultant calcine sent to the copper department.

The benefits from copper in a lead smelter are as follows:

1. Better sinter and a good furnace tonnage, especially if chalcopyrite.
2. If a baghouse is used to collect the sinter fume, the bag life will be aided by copper as a more alkaline dust will be produced at the sinter machines

with slightly more fume.

3. Copper has a great affinity for arsenic and will prevent the arsenic from entering the lead bullion. I have seen the reduction badly off on a lead furnace, even up to 2.5 pct lead in the slag, with 4 pct copper and 2 pct arsenic on the furnace charge, yet the bullion was below 0.1 pct As.

The problems from copper are as follows:

1. Lead wells are apt to be useless and on high copper charges, with the lead removed through the first settlers, the copper will cause a hotter lead and probably result in more frequent tap-hole changes.
2. More dross-fall and creating problems at the drossing kettles.
3. More cost at dross reverberatory to work up the dross.
4. Higher metal losses in dump slags.

Conclusions

1. Copper will not affect the operation of a lead blast furnace, if in the form of a well roasted sinter; but if contained as a dross, definitely it will.
2. Copper will not affect the fume or flue dust production on the blast furnace.
3. Copper will not affect the reduction on a lead blast furnace.
4. Copper will affect the secondaries produced—thus more dross-fall.
5. Copper will affect the slag losses.
6. Copper will affect and produce a hotter lead.
7. Copper will affect and cause lead-well trouble.

Thus, it is preferable to remove copper at the lead concentrators and make a copper concentrate which can be shipped to a copper smelter. In this way, the copper losses will be considerably lessened, for a lead plant will show possibly a 10 pct copper loss depending upon conditions, against a copper smelter's loss of, say, 2 pct. In addition to the extra losses in the lead plant, one must consider the higher as well as additional processing costs which are incurred when any copper is routed into a lead works, since any copper into a lead smelter must eventually be sent to a copper plant to be worked up into blister copper.

Therefore, to conclude this paper, the writer believes that with the present high metal prices the benefits, such as are obtained in the sinter and the baghouse aids, are apt to be outbalanced by the increased costs for processing and the metal losses.

What Is Metallurgy?

JOHN CHIPMAN,* Member AIME

There is no better way of paying tribute to the memory of a scientist than by developing and carrying forward those ideas which he has contributed to science and which are for us the very essence of his immortality. For a lecturer who has not had the great privilege of studying under Professor Howe or even of knowing him in person, these ideas must be transmitted through the printed word. It is our great good fortune that Professor Howe left to us a rich heritage of publication, not only in his classic monograph on the "Metallography of Steel and Cast Iron" but in a wealth of earlier books and papers in the transactions of this Institute and of other scientific and engineering bodies. An outstanding characteristic of this published record is the great breadth of interest and of vision which it portrays. His was not a narrow specialization in only the scientific aspects of ferrous metallography. On the contrary many of his important contributions had to do with a far broader field of metallurgical endeavor. He insisted that his students be well grounded in the fundamentals underlying the whole field and not led into the narrow groove of specific applications. Among his first major publications we find papers on copper smelting, extraction of nickel, the efficiency of fans and blowers, thermic curves of blast furnaces, the cost of coke, and the manufacture of steel. These are the papers of a metallurgical engineer and it was among engineers that Henry Marion Howe made his early and well-merited reputation.

These early engineering contributions display very clearly the strongly scientific inclination of their author.

The classic work on "The Metallurgy of Steel" published in 1890 contains a thorough and critical discussion of all that was known at the time concerning the alloys of iron and of what we would now call the physical metallurgy of steel. In addition it describes steel-making processes in use and some that had become obsolete, and points out in critical fashion the reasons for success and failure. Steel mill design and layout were included as well as some pertinent discussion of refractories. The book is indeed an embodiment of one of Howe's outstanding characteristics—breadth. It is both the science and the engineering of steel production as known in that day.

One of Howe's earliest technical papers was entitled "What is Steel?" That was nearly seventy-five years ago when many new processes and new kinds of steel were being developed. The time was ripe for such a question and the answers which Howe was able to give were helpful in understanding the phenomena of heat treatment. Twenty-five years ago Professor Sauveur repeated the question as the title of the first Henry Marion Howe Memorial Lecture. It seemed to him that this question, "What is Steel?," had served as Howe's motto throughout the remainder of his life.

Today I shall present for your consideration a question of another sort: "What is Metallurgy?" Perhaps it is not too much to hope that in the answer we may obtain a clearer and possibly broader view of the nature of our

science and our profession. The time is ripe for giving careful consideration to what we mean by metallurgy. If our Metals Branch is to become in fact an American Institute of Metallurgical Engineers, it is essential that we understand what is meant by metallurgical engineering. I am convinced that the best interests of the profession have not been served by a narrow interpretation of these terms. We must now place emphasis on the breadth of metallurgy as a science and as an engineering profession.

With its usual brevity and wit, Webster's dictionary defines metallurgy as "the science and art of extracting metals from their ores, refining them and preparing them for use." I shall not assume that the words "science" and "art" and "metal" are so well understood as to require no defining but others among our contemporaries are better qualified than either your lecturer or the dictionary to present the broad meanings of these terms. When we say that metallurgy is among the oldest of the arts we are not classifying it with painting or sculpture or music but rather with the making of tools or weapons or the building of bridges or chariots or cathedrals. In short we are saying that metallurgy is among the oldest of the engineering professions.

The question "What is metallurgy?" has been one of rather more than ordinary concern to those of us who have the task of developing a curriculum for the education of students in this field. This development has been going on in a number of universities over a period of some years, but there seems to be as yet no unanimity as to what such a curriculum should contain. I believe there is fairly complete agreement that it must be founded upon sound

San Francisco Meeting, February 1949.

Howe Memorial Lecture.

TP 2614 C. Manuscript received March 7, 1949.

*†Department of Metallurgy, Massachusetts Institute of Technology.

basic training in the sciences and that it should contain the elements of an engineering education. The recognition of metallurgy as both science and engineering is fairly widespread among metallurgists. It is not so well understood in other circles.

The terms "metallurgy" and "metallurgical engineering," if each is used in the broadest sense, mean exactly the same thing. I know of two metallurgical departments that have similar curricula, one of which graduates metallurgists, the other metallurgical engineers. For purposes of this discussion, however, I shall use the term "metallurgy" as the broader one to include on the one hand metallurgical engineering and on the other the science of metals.

In connection with our efforts to establish a rational curriculum for students of metallurgy we thought it would be extremely helpful to have before us a concise outline of the entire field. Now it is no small task to prepare such an outline. Metallurgy is a large subject and it overlaps many others so that a clear-cut line of demarcation between it and its neighbors cannot be drawn. The various parts of metallurgy are closely interrelated and cannot be divorced. Nevertheless it is possible to set down in some sort of logical sequence the names of the principal parts of the science and art of extracting metals from their ores, refining them, and preparing them for use.

In presenting the outline I must emphasize that, while the chief impetus for its preparation was pedagogic, it is in no sense an outline of a curriculum. It is not my intention to discuss the pros and cons of the several items which compose the academic bill-of-fare. But this outline which evolved in the course of such discussions may have other than academic uses, and moreover the purpose for which it was developed can best be served by offering wide opportunity for criticism.

There is no universally accepted terminology corresponding to that used in the outline. Other schemes of classification have been employed, for example, "extractive metallurgy" may cover not only the first two engineering divisions and "adaptive metallurgy" the other two, but each term may include also the appropriate parts of metallurgical science. Similarly the term "production metallurgy" could be used to cover some eighty percent of what I have called "metallurgical engineering." Two terms which are conspicuously absent from the outline

A. Metallurgical Engineering

Extractive Metallurgy

1. Mineral Dressing

- Comminution of ores
- Separation of minerals
- Leaching

2. Process Metallurgy

- Roasting and sintering
- Reduction and smelting
- Fuels and combustion
- Refractories and furnaces
- Heat and fluid flow
- Electrometallurgy
- Melting, refining and alloying
- Casting and solidification

Adaptive Metallurgy

3. Metal Processing

- Hot and cold forming
- Foundry practice
- Joining
- Surface treatment
- Powder metallurgy
- Heat treatment

4. Application Metallurgy

- Quality control
- Selection and specification
- Alloy design
- Service behavior

B. Metallurgical Science

1. Chemical Metallurgy

- Crystal chemistry and mineralogy
- Thermodynamics
- Reaction kinetics
- Surface chemistry
- Electrochemistry
- Corrosion

2. Physical Metallurgy

Metallography

- Constitution and phase diagrams
- Macro, micro and lattice structure
- Grain size and texture
- Grain growth and recrystallization
- Phase transformations

Physics of Metals

- Electrical and thermal properties
- Atomic bonding and cohesion
- Magnetism
- Diffusion
- Theory of the solid state

Mechanical Metallurgy

- Elasticity
- Anelastic behavior
- Plastic flow and work hardening
- Rupture and fatigue
- Creep
- Correlation of structure and mechanical properties

are "ferrous" and "nonferrous." These terms may be useful industrially but the division of science or engineering along such lines would not be profitable. I have no quarrel with those who would select a different set of words nor indeed with those who would interchange the terms "metallurgy" and "metallurgical engineering."

There is of necessity much overlapping in the outline, just as there must be in any attempt to set forth the content of any science. There are interrelationships throughout the outline so numerous that any attempt to show them by subheadings and tie-lines would simply cross-hatch the entire page. The purpose of the outline is not to divide metallurgists into classifications but rather only to simplify the task of examining our metallurgical profession to find out what it contains. To continue this study of the anatomy of metallurgy, let us consider briefly each of the major divisions of the outline.

Metallurgical Engineering

Metallurgical engineering is the direct descendant of that ancient art first brought to man by the titan demigod Prometheus. He it was who dared oppose the will of newly-crowned Zeus when that cruel monarch planned to sweep mankind off from the world and plant a newer race there. He stole fire from heaven and brought it down to earth for men to use. He taught men the motions of the stars and devised for them numbers and letters. He originated ships and was first to yoke horse to chariot. And, in the words of this first metallurgical engineer:

"For the other helps of man hid underground

The iron and the bronze, silver and gold
Can any dare affirm he found them out
Before me? None, I know! unless he
choose

To lie in his vault. In one word learn the
whole—

That all arts came to mortals from
Prometheus."

MINERAL DRESSING

Metallurgical engineering begins with what is "hid underground," the ore, thus illustrating a constantly recurring phenomenon, that the metallurgist is intimately concerned with nonmetals. Metallurgy must in practice begin with the ore and its first operations are those of mineral dressing. Here it is very closely allied to such fields as solid fuels, ceramics and nonmetallic minerals and like them it is here intimately associated with economic geology and mining. In brief this first segment of metallurgy constitutes also a portion of a broad field which is quite properly termed mineral engineering. Much of the scientific background lies in the fields of crystal chemistry, surface chemistry, mineralogy, hydrodynamics and other branches of knowledge not too familiar to most metallurgists but indicative of the breadth of the field.

The importance of the field is obvious in that almost every ore that comes from the ground requires some processing before smelting or reduction can be undertaken with profit, and it will not be many years before the word "almost" can be omitted. The very question of whether or not a given deposit can be considered an "ore" is conditioned upon the state of the mineral dressing art. The ores from which

the bulk of our copper is now produced were of no value fifty years ago. The development of flotation converted worthless rock into a natural resource. Much of our iron ore of the future must come from rock which today cannot profitably be smelted. We face here one of the great tasks of metallurgical engineering.

PROCESS METALLURGY

Process metallurgy has a long and honorable history too familiar to most metallurgists to require discussion. This is the very stuff on which the Iron and Steel Division is made. It is the succession of steps or processes by which impure mineral is reduced to metal, refined, alloyed and delivered according to a specification. It is an old art, but with the aid of chemical science it has become a chief part of modern metallurgical engineering. It is closely akin to chemical engineering with which it has many ideas and problems in common. The study of the field in terms of processes rather than by metals here follows the lead of chemical engineering education with its emphasis on the "unit processes."

It is worth noting that process metallurgy is not narrowly concerned only with the metal it produces. It has much to do with nonmetals. Operations begin with minerals and fuels and refractories, and the use of these materials is an essential part of the whole. In nearly every melting process a non-metallic by-product, a slag, is formed and in many cases this slag is itself a necessary reagent for carrying on the chemical reactions of the process. The chemistry of slags and of slag-metal reactions is extremely important in the control of such processes.

Process metallurgy is concerned also with certain principles which are common to many processes. Among them may be mentioned the flow of gases, combustion, heat flow, material balances and yields, heat balances and thermal efficiency, rates of reactions and the laws of chemical equilibrium. It is the quantitative application of such principles in the smelting and refining of iron and steel which has been the guide to efficient utilization of pressure and of oxygen and which will continue in the future to point the way to new efficiency and economy.

METAL PROCESSING

The more physical aspects of production metallurgy, the methods of

forming into useful shapes, are grouped in the outline under *Metal Processing*. Among these we note the overlapping of metallurgy with recognized trades or professions such as welding, founding, forging, electroplating. These fields are as much parts of metallurgical engineering as are steelmaking or heat treatment, and they deserve as much interest and recognition on the part of the metallurgical profession. For too long a time they have been relegated by metallurgists to rule-of-thumb control. Much can be accomplished here by the application of science and of sound engineering as witness recent advances in welding and the current renaissance in the foundry industry. Here we have seen in recent years the doubling of the strength of gray iron by persuading the graphite to form nodules rather than flakes. We have seen more than the doubling of the dependability of steel castings through control of soundness.

APPLICATION METALLURGY

The task of putting the right metal in the right spot with full regard for cost and service is an important part of metallurgical engineering. The selection and specification of metals and of their heat treatment is often a task of large proportions involving all the skill and understanding of an experienced metallurgist. The more complex the structure, the more kinds of metals must be taken into consideration; the greater the quantity of production, the more urgent it becomes to select for each part the right alloy, the right quality, for economic manufacture and service. It is in this field particularly that the science of physical metallurgy finds its practical engineering applications, and that metallurgy becomes the servant of all engineering. The metallurgist is constantly working with and for engineers of different backgrounds. He must know their language. He must understand the rudiments of design, of stresses and vibration, of fabrication and inspection and assembly. His success is gauged by his ability to serve his fellowman in adapting the right metal for each use.

Then comes the time when there is no satisfactory metal known for the given task; a new alloy must be designed to fit the job; a research and development program is required. As alloys are obtained which fill the need the requirements go up, still better alloys are required and the process

must continue. We are constantly in the midst of such developments, rapid progress being made at present in the development of high-temperature metals. The design of a new alloy for a given purpose may be a very simple or an extremely difficult task, depending upon the availability of basic scientific data needed. The development of our N. E. steels during the war was an example of alloy design on a grand scale, the success of which was assured by adequate knowledge of such controlling factors as steelmaking practice, strength, ductility and hardenability.

Metallurgical Science

A celebrated nuclear physicist when asked "What is the difference between science and engineering?" replied, "About fifteen years." He implied that it takes engineering about fifteen years to utilize the new things of science.

No one believes that the full engineering use of nuclear fission can be developed in any such short time, but it is true that the nuclear engineering tasks which have already been accomplished (the bomb, and commercial production of radio-isotopes) required much less. In metallurgy the difference in time is likely to vary from plus fifty to minus fifty years. Many a scientific result is left to molder on the shelf for years while others which appear to offer the prospect of economic reward may be converted into engineering application with breath-taking speed. On the other hand engineering developments frequently must be pushed forward without benefit of science. In Professor Howe's view engineering is essentially application, while the function of science is correlation with or without discovery. In 1917 he said: "Pure science in its relation to engineering seems today to be in an intermediate stage of its asymptotic evolution from the state of a follower to that of an absolute dictator." As one who has spent some years in study of the science underlying the art of steelmaking, I feel privileged to say that it is a blessing to humanity that the development of steelmaking practice did not have to await the full understanding of the scientific principles upon which it rests. At the same time I must express the conviction that the science will become more useful to the art as its growth progresses—indeed that it will approach asymptotically,

as Professor Howe has said, although it can never quite reach the state of "an absolute dictator."

CHEMICAL METALLURGY

The great dependence of process metallurgy upon the basic science of chemistry has been illustrated many times in such activities as the operation of blast furnaces and open hearths and the smelting and refining of all sorts of metals.

Production processes require time; hence, the rates of reactions, the rates of transfer of impurities such as sulphur from metal to slag, the rates of reduction of oxides and other phenomena of chemical kinetics are important to nearly every process. Of perhaps even more basic importance is the question whether or not a proposed reaction will occur at all. We do not make aluminum or zinc in a blast furnace, much as we should like to do so if it were possible. There is also the question of how far a process will go before it reaches equilibrium and finds itself run down like a clock. We do not get all the carbon or sulphur or phosphorus out of a heat of steel for just this reason. Consider the slags which are so important in the conduct of smelting and refining processes. We used to think of them as being made up of various mineral species. Some of us liked to regard them as molecular solutions. Nowadays it seems more probable that they are made up chiefly of ions, electrically charged atoms or groups of atoms, some of the groupings being fairly complex. There is much that is not yet known about slags but a knowledge of their actual structure would undoubtedly aid in understanding their proper control. These are chemical questions and illustrate the dependence of all of our processes upon chemical metallurgy, particularly upon kinetics and thermodynamics.

Certain metals which have only recently come into use and others which, like titanium, are still in the chemical stage give added emphasis to the close relationship between chemistry, process metallurgy and chemical engineering. Every new metal that is brought into use will bring its own problems and its own chemical processes. Many of the metals which are now shrouded in obscurity will inevitably be brought into practical use in the years to come. By the time our metal-hungry civilization has become sufficiently discriminating to demand

the highly individualistic properties of some of our rarer metals we will witness the introduction of new and strange methods of production. The metallurgy of gadolinium or dysprosium, for instance, may well involve such processes as solvent extraction, ion exchange, fractional distillation, fluorination, and electrolysis. These are the things which chemistry has in store for metallurgists and they will become as much a part of process metallurgy as the blast furnace or the converter.

Our interest in chemistry must not end with the production of the metal. Reactions occur within the solid and it is these reactions which provide the basis for heat treatment. Reactions occur also on the surfaces of metals and these provide troubles aplenty for all who are concerned with their service behavior. The control of metal corrosion has become an important engineering activity, but in spite of the great advances that have been made, the world's corrosion bill amounts to several billion dollars every year. The scientific study of corrosion is an important part of chemical metallurgy. To the metallurgist it is obviously dependent upon many factors which we think of as physical metallurgy, since the corrosion behavior of a metal depends not alone upon its chemical nature but upon its structure. But it is highly dependent upon its chemical environment, its electrical contact with other metals and upon that physico-chemical super-mystery, passivity.

PHYSICAL METALLURGY

Physical metallurgy is the science of the metallic state. Offspring of physics and physical chemistry, it is intimately concerned with the structure of metals and alloys and with the phenomena which occur within this structure. The study of metal structures and of the processes which determine them is called *metallography*. It is regrettable that this term has become widely used to connote only the microscopic observation of structure. Its real significance is far wider. In its broad sense it signifies the whole science of metal structure. This includes all knowledge of equilibrium in metallic systems as shown in the many phase diagrams that have been published and the nearly infinite number which remain to be studied. It includes recrystallization and grain growth and precipitation within metallic phases. The whole complex series of changes, by which soft

austenite is converted into tough bainite or hard martensite and the latter is tempered to produce structures of desired properties, is a part of this science of metallography. It was in this broad sense that Professor Howe used the word in his "Metallography of Steel and Cast Iron," and I urge that we return to this usage.

Progress in the development of new alloys as well as in understanding and improving the old ones, would be materially accelerated by a more thorough understanding of the nature of the solid state. The forces by which the atoms are bound together in a crystal are far greater than the overall strength of even our best metals. Why cannot we utilize all of this force to produce a steel ten times as strong as our present strongest? Atoms are bound together by electronic forces. Do the electrons spread throughout the structure as a sort of cloud, or do they resonate between several alternative interatomic positions? The answer lies in electrical, magnetic and thermal properties of alloys, and although we do not yet know how to read this answer, we may be confident that it will ultimately play its part in attaining such practical ends as the making of stronger or more ductile steels. The search for a better understanding of the solid state is not something that the metallurgist can leave entirely to the physicist. The two must work together as both kinds of background are needed. The *physics of metals* is an essential part of metallurgy.

Metals are useful primarily because of their mechanical properties, their strength, ductility, elasticity. The study of such phenomena is *mechanical metallurgy*. The metallurgist's approach to studies of elastic and plastic deformation is basically different from that of the mathematical stress analyst. A metal is not a mere three-dimensional continuum possessed of properties expressible in differential equations. It is a complex aggregate of crystals which may differ greatly among themselves and whose properties may change with strain and with time. Why does such an aggregate fail under load, and how? What is the mechanism of the characteristically metallic phenomenon called slip? Why and how are blocks of metal atoms able to glide for great distances over slip planes? Do they really behave like a panful of soap bubbles? By blocking slip planes we can raise the tensile strength. When are we going to learn to do this so effectively as to double the useful strengths of steels?

The Province of Metallurgy and Neighboring Areas.

Metallurgical Education

One of the principal reasons for asking the question, "What is metallurgy?" has been the need for a system of guide-posts along the road to metallurgical education. With the outline acting as a small-scale map of the province let us have a brief look at the path which a student may follow. One fact stands out clearly—the area is large and the terrain in some parts is rugged. The neophyte, planning to spend four years in becoming acquainted with the area, cannot hope to have time to dig deeply into each interesting vein nor to pick all of the daisies that he passes in the field. In planning his tour we must assure that he has an opportunity to see at least a part of each principal area. We must reserve enough time on his itinerary for him to examine in some detail the areas in which he is most interested and we must see that he is equipped with tools for digging in these areas. In addition we must recognize that he is going to spend a part of his time in daisy-picking and other nontechnical activities and we should teach him the difference between wild grape and poison ivy and how to avoid the pitfalls and the rattlesnakes. In introducing him to the province of metallurgy we must see

that he learns to mingle not only with his fellow explorers but with the great variety of people whom he will encounter within the field and in adjacent areas.

It is neither feasible nor desirable that all students who spend four years in metallurgical study be subjected to the same instruction. The world has need for many kinds of technically trained people and indeed many kinds of metallurgists. Happily there are enough individualists among metallurgical educators to provide a variety of curricula at the several institutions that offer the subject. In general, departments of metallurgy or of metallurgical engineering have given heed to Professor Howe's warning against Procrusteanism. "You remember Procrustes," he said, "who made his bed fit every traveler by lopping off the tall one's legs and stretching the short ones on a rack. Beware the narrow and cocksure Procrustean of every walk of life who would have all institutions shaped to fit their own pet ideals regardless of the need of the world of widely different products."

Perhaps it is not generally recognized outside of academic circles that a student of metallurgy devotes only about one-third of his effort during a four-year course to studies of metal-

lurgy. One half of his time is spent on basic science and engineering. This provides a minimum of preparation for entering and exploring the province of metallurgy. Nearly one-fifth is spent on the arts and humanities (daisy-picking and mingling) and this leaves less than one-third for metallurgy. Now it is obviously impossible to cover all that is included or implied in our outline of metallurgy in one-third of a four-year course. A large amount must be omitted and in fact should be. It is quite feasible, however, to teach the fundamental principles underlying most of the subjects listed, provided the student is not overburdened with mere description or with a plethora of specific applications. These rather bare fundamentals plus one or two advanced or specialized studies and a thesis requiring independent laboratory work on a subject, preferably of the student's own choosing, complete the metallurgical part of his schooling.

It is far more important that the student have a real grasp of physical chemistry than that he know the dimensions of the biggest blast furnace or the latest wrinkle in instrumentation. It is far more important that he understand what goes on inside a piece of steel during heat treatment than that he be able to distinguish between

bainite and fine pearlite under the microscope. It is far more important that he be able to *think* than that he know the characteristics of a wide variety of alloys. And it is in the teaching of the fundamentals that the instructor has his best opportunity to help the student learn to think. It seems perfectly clear to me that no part of the fundamentals of metallurgy should be omitted in order to substitute a college professor's idea of how an open hearth furnace ought to operate!

I have been talking of undergraduate instruction; what about postgraduate study? For the great majority of metallurgists this is directly related to a job and is therefore specialized. In many industries definite and well-planned training programs have been set up; these are of very great value to the young metallurgist and to the industry as well. The modern scheme of engineering education is becoming more and more dependent upon such training, and both the universities and the industries are according greater recognition to the responsibilities of the latter in the training of engineers.

Graduate training in the universities generally has one or the other of two objectives: further preparation for a professional career by extension of

undergraduate training both in breadth and in depth along some one or two lines of specialization; or preparation for a research career or for leadership in some field in which research plays a dominant part. In a field that is as young and vigorous as metallurgical science, graduate work has much to recommend it. It is, however, by no means to be regarded as a necessary part of a metallurgical education for those whose undergraduate training has been sufficiently basic and sufficiently broad.

Summary

In summary permit me to repeat that metallurgy is a field of great breadth. Since it is inhabited by metallurgists these must be people of wide vision. I have heard important persons who ought to know better speak of metallurgy as a narrow field of specialization. Nothing could be farther from the truth. It does, of course, contain within its boundaries many fields in which a metallurgist may specialize to his heart's content. But no other branch of engineering can compare with it in breadth if that breadth be gauged by the number of other fields

with which it has a common frontier. No other field of applied science draws so heavily upon both of the two basic sciences of physics and chemistry. No field of endeavor exhibits a greater wealth and diversity of achievement. Nowhere can scientists of such a wide variety of interests find a more fruitful or more stimulating field for research.

And now we must attempt to answer the question "What is a metallurgist?" Surely there must be thousands of answers to this question for it is obvious to any observer that no two metallurgists are alike. If we state that "a metallurgist is one whose scientific or professional work is directed toward the production or use or understanding of metals," what more need be said? We have here a definition broad enough to include all of us. However, it is too broad; it needs to be made specific; it requires illustration. Let us add then—"like Henry Marion Howe." And we have no longer a mere definition but an aspiration. For here was a man whose memory still inspires us. Here was a metallurgist whose interests reached into every corner of the province of metallurgy, whose work has influenced every segment of metallurgical science and engineering.

The Sigma Phase in Ternary Cr-Co-Fe and Cr-Co-Ni Alloys

PAUL A. BECK,* Member and W. D. MANLY,† Junior Member, AIME

In a recent note Sully and Heal¹ showed that the Cr-Fe sigma phase is isomorphous with the Cr-Co gamma phase, and that the lattice constants are also nearly identical. In a preliminary investigation of the ternary Cr-Co-Fe system at 800°C at this laboratory the above findings were confirmed, and it was found by microscopic techniques, using various etching reagents, that the two binary phases form an uninterrupted series of solid solutions with each other. These solid solutions occupy a straight narrow band which cuts across the 800°C isothermal section of the ternary system, connecting the two binary phases.

A detailed investigation of the Cr-Co-Ni ternary system at 1200°C

disclosed that here, too, the Cr-Co gamma phase extends deep into the ternary system in the form of a long narrow lip. The fact that this sigma type lattice is sustained even when well over half of the Co atoms in it are replaced by Ni atoms, with relatively little change in the Cr content, clearly indicates that Ni itself has a certain

tendency to form the sigma phase with chromium. This tendency is hidden in the binary Cr-Ni alloys, where the sigma phase is not known to occur, but it becomes operative in the presence of a sufficient amount of Co. The interpretation of these facts in terms of electron concentrations is rendered difficult by the uncertainty of our present knowledge of the valency electron structure of the transition elements in their alloys. However, Sully and Heal's results and the present work suggest that intermetallic phases with sigma type lattice may occur more frequently in these little investigated alloys than heretofore suspected. In particular, it is expected that a similar phase may exist in the V-Co and perhaps in the V-Ni system, in analogy to the known sigma type phase in the V-Fe system, and that all these sigma type phases may form extensive solid solutions with one another.

Distillation of Zinc from Copper Base Alloys and Galvanizers Drosses

FRANK F. POLAND*

The purpose of this paper is to describe the recent applications and improvements made in the process and equipment for the recovery of metallic zinc from secondary metals by means of high temperature electric resistor furnace distillation.

The process and high temperature furnace, as developed by Revere Copper and Brass Incorporated, Research and Development Department, was described in a previous paper.†

Since the publication of that paper the process and equipment have been licensed to others. Consequently its field of application has been expanded, particularly for the treatment of scrap brass, galvanizers dross and scrap zinc. Other applications are being considered, particularly the melting of metallic titanium and special alloys requiring a controlled atmosphere. Consideration is also being given to modification in design that would allow the melting of copper cathodes for the production of oxygen-free and electrolytic tough pitch copper shapes without the necessity of blowing and poling.

In the design of a furnace for melting copper cathodes it is intended that the fundamental principle of charging the solid material into a large pool of molten metal through a double door charging vestibule as shown in Fig 3 of the previous paper,† would be adhered to and, in addition, either dehydrated and desulphurized producer gas or commercial nitrogen, that is, approximately 96 pct nitrogen, 2 pct hydrogen 2 pct CO, also dehydrated, would be

used to provide a protective atmosphere for the resistors and to flush out more soluble gases from the molten copper.

The operation of a small unit producing approximately 1000 lb of copper per hr has shown that the commercial nitrogen will allow the production of tough pitch electrolytic copper when the metal is transferred from the melt-down unit contemplated to a special type induction unit where the oxygen absorption and temperature can be controlled.

Standard practice in treating low grade scrap brass has been to oxidize the zinc by blowing air through the molten metal. This operation results in the recovery of approximately two-thirds or less of the zinc content of the brass in the form of an impure zinc oxide having only a fraction of the value of the zinc in metallic form. The balance of the zinc is lost to slag, fume and drosses. Fig 1 shows the revised flow sheet of the process for the treatment of scrap brass. For this application and as shown on the flow sheet a low frequency induction furnace has

been substituted for the Wilkins-Poland type as a melting unit. This type of furnace has been found the most suitable for the purpose as will be shown by the following discussion.

Scrap Brass

The melting of refinery scrap brass preparatory to distillation presents a melting problem quite different from the usual melting of brass mill scrap for recasting because refinery scrap is a heterogeneous mixture of alloys each having different melting and boiling points, and coated with a variety of corrosion products and foreign materials. In addition, brass and copper plated pieces of sheet iron, stainless steel, ceramic materials, and others are present that do not melt except at temperatures above the boiling point of the liquid bath.

In the previous paper it is noted that difficulty was encountered in the melting of refinery grade scrap brass without excessive loss of zinc by volatilization and that 5 to 10 pct razorite flux was used to alleviate this condition. While this flux was successful in preventing the excessive loss of zinc by volatilization it interposed a low heat conductivity layer between the source of heat and liquid charge and resulted in lowering the melting rate of the furnace. This same problem presents itself in all types of furnaces in which the metal is heated by radiation and conduction from above the charge.

It has been found in melting this type material that the melting rate per hour or per square foot of hearth area

San Francisco Meeting, February 1949.

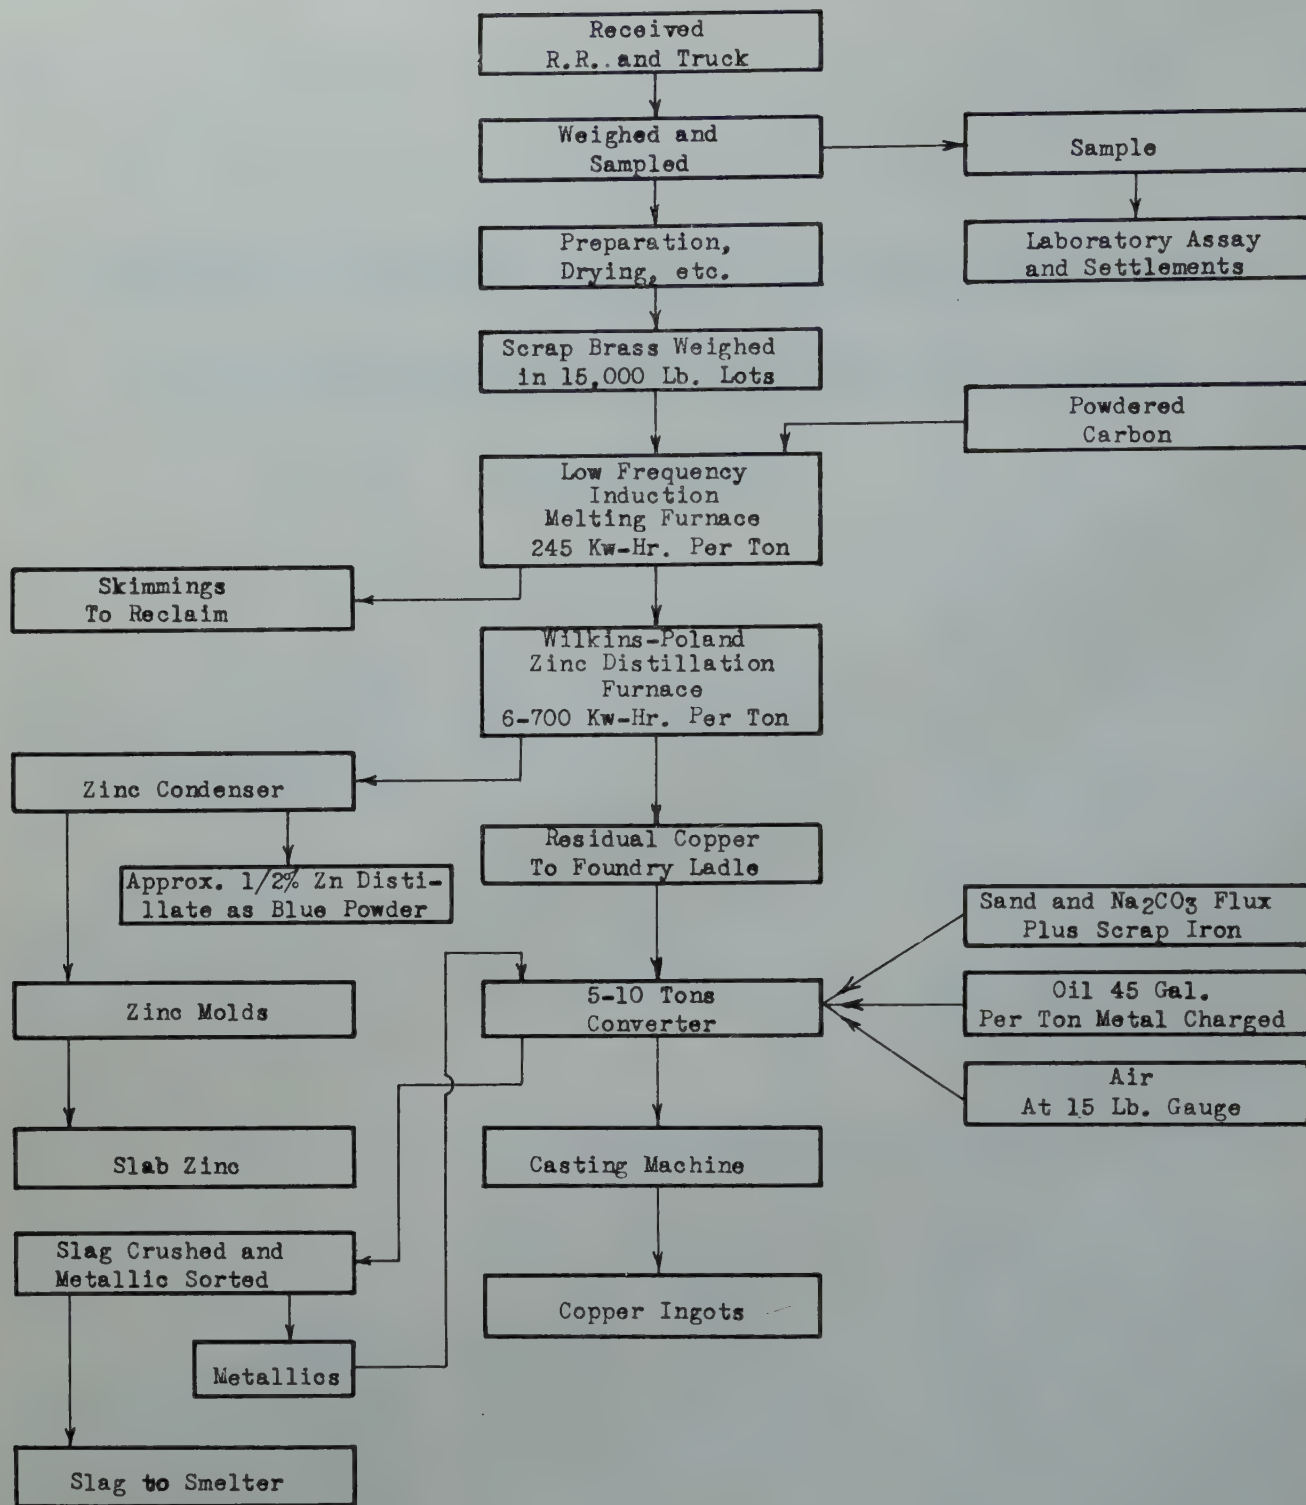

FIG 1—Flowsheet of process for treatment of scrap brass.

for all types of furnaces is considerably less (of the order of 50 pct) than when the same furnace is used for melting scrap alloys or metal of a uniform composition. Allowance for this difference in melting capacity for any given size furnace must be made when designing the melting equipment.

The induction type furnace, because

of its generating heat in the charge below the surface, allows the use of a flux or carbon cover so that the benefits of such a cover may be obtained without interference with the heat input to the charge. This type furnace is constructed without any cover or roof which is an advantage in charging bulky material and allows the use of

mechanical means for pushing the cold charge into the liquid bath.

The usual secondary winding, that is, heating ducts, in induction furnaces designed for general brass mill casting are not satisfactory for the melting of low grade scrap because this type material does not ordinarily contact the liquid metal enough to absorb the

full rated energy of the furnace, consequently the metal in the secondary boils, pinching off and thereby reducing the power input. A low frequency furnace designed for this particular purpose has larger ducts and more circulation than normally supplied and, in addition, is provided with hydraulic rams to push the cold charge into the liquid bath.

The amount of dross formed when melting this type scrap is ordinarily much greater than that produced when melting scrap brass of uniform composition or even when melting turnings. However, it has been found that a layer of two or more inches of finely divided carbon, or preferably lamp-black, on top of the liquid metal, used in conjunction with a hydraulic ram increases the rate of melting to a maximum and reduces the loss of copper and zinc to skims and fume to a minimum.

The finely divided carbon cover on top of the liquid metal produces a very strong reducing atmosphere at the melting zone and experiments have shown that this atmosphere, high in carbon monoxide, will reduce zinc oxide to metal.

Consequently this is an ideal condition and one that is difficult if not impossible to reproduce commercially in any other type of melting furnace.

In melting clean scrap brass, such as mill scrap that contains no ceramic material or other contaminants, there is practically no loss of zinc when melting under the finely divided carbon cover. From these considerations it is believed that the loss of zinc to skims and fume in melting under the conditions described has been reduced to an absolute minimum. The effects on the economics of the operation are shown by the following metallurgical results.

METALLURGICAL RESULTS

The following are the results obtained from the treatment of a mixture of approximately 1,000 tons of light and heavy miscellaneous yellow brass scrap melted in a low frequency induction furnace equipped with mechanical pushers and using a carbon cover on top of the liquid metal.

The approximate analysis as charged to the induction melting furnace was copper 64.2 pct, zinc 25.5 pct, lead 2.0 pct, tin 1.0 pct, nickel 0.7 pct, aluminum, silicon, manganese 0.3 pct, iron (varies widely) 3.3 pct, infusible material, oil, other combustibles, H₂O, etc., 3.0 pct.

There was produced the following, as indicated in Table 1:

| Table 1 . . . Production | | |
|---|---------------------|--|
| | Pct Gross Scrap | |
| Melting furnace skims..... | 7.7 | |
| Zinc slabs..... | 21.4 | |
| Blue powder..... | .5 | |
| Residue copper..... | 67.9 | |
| Volatile and combustible loss..... | 2.5 | |
| | 100.0 | |
| Approximate Zinc Distribution | Pct Gross Scrap | |
| Zinc slabs..... | 21.4 | |
| Blue powder..... | .5 | |
| Melting furnace skims at 15 pct zinc..... | 1.2 | |
| 2.7 pct of residue copper..... | 2.0 | |
| Fume..... | .4 | |
| | 25.5 | |
| Zinc Recovery | Pct Zinc Contents | |
| Zinc slabs..... | 83.9 | |
| Blue powder..... | 2.3 | |
| | 86.2 | |
| Sub Total Recovery..... | | |
| Distribution of Zinc Losses | | |
| to melting furnace skims..... | 4.5 | |
| to copper shot..... | 7.8 | |
| volatile..... | 1.5 | |
| | 13.8 | |
| Sub Total Losses..... | | |
| Total..... | 100.0 | |
| | Pct Copper Contents | |
| Copper produced in residue metal..... | 96.5 | |
| to melting furnace skims..... | 3.5 | |
| | 100.0 | |
| Total..... | | |

Melting in the reverberatory or converter type furnace results in a zinc loss to slag and fume of between 18 to 30 pct, a fair average being about 23 pct of the total zinc contents. The copper loss to skims is also proportionately greater than in the induction furnace.

The increased amount of zinc lost and the additional amount of by-products to be treated for the recovery of copper results in an estimated difference in returns of approximately \$20.00 per ton of scrap brass treated, in favor of the induction furnace.

The amount of zinc left in the residual copper from the distillation is under the control of the operators and it has been commercially varied from less than 1.5 to 3.5 pct depending upon the planned disposal of the residual metal. The results enumerated above were predicated upon a use where it was desirable to obtain the maximum production and anything under 3 pct zinc in the residual copper was adequate. The temperature of the residual copper as tapped from the distillation furnace was approximately 3200°F. However, these furnaces have been run for considerable periods at much higher temperatures, and in one plant the operating temperature is sufficiently high to reduce the zinc content of the residual metal to less than 1.5 pct. This corresponds to a metal temperature of approximately 3500°F.

There have been no changes made in the condenser or furnace operating temperature from that described in the previous paper. Therefore the copper content of the zinc slabs produced is approximately the same, that is, 0.75

pct. The lead content of the zinc produced was 3+ pct which is normally liquated to Prime Western quality.

In general, it has been found that from 35 to 45 pct of the lead content of the scrap metal is distilled with the zinc. All of the other contaminants have very low vapor pressures at the operating temperatures and consequently copper and lead are the only metals in significant quantity carried to the condenser by the zinc vapor.

CONVERTING RESIDUAL METALS

Since the publication of the previous paper the plants that have installed this equipment have desired the residual metal for purposes different from those described in that publication. In one plant the residual metal was intended to be made into shot for the manufacture of copper sulphate. In another the residual metal was intended for electrolytic copper refining and in others the residual metal was to be converted for use in the manufacture of copper base ingot alloys. The revised flow sheet (Fig 1) shows the use of a 5 to 10 ton converter instead of the 50 ton previously described. In operating this small converter the residual metal is transferred directly from the distillation furnace and copper oxide added in definite amounts or air blown through the metal to some definite control point, for instance, iron to -0.02 pct, depending upon the end uses as enumerated above. There is nothing particularly new in this general operation. However, it is believed of interest to note that the iron can be reduced to the third decimal point in percentage while 0.75 to 1 pct zinc is still present and that in so doing only about 10 pct of the lead and tin present is removed. After the iron is removed the zinc, tin, lead and nickel are eliminated concurrently but in the order given.

It is common practice in recovering zinc from galvanizers dross to use the retort process. It is well-known by those operating such equipment that it is becoming more and more difficult to obtain labor that is willing to perform the hot, smoky and dirty task connected with this process.

One of the Wilkins-Poland units designed for handling scrap brass was modified to permit a pilot plant operation on the distillation of galvanizers dross, scrap die castings and other scrap zinc and subsequently the engineering company licensed to build these furnaces has designed a unit especially

adapted for this purpose. This unit consists of a special type low frequency furnace connected directly to the Wilkins-Poland distillation furnace of standard type.

Table 2 summarizes the results of the pilot plant operation, the estimated cost and the savings to be made. The comparison has been based on the operation of one Wilkins-Poland unit of 750 KVA capacity which is capable of processing 15 tons of dross per day vs. a retort plant equipped with 10 retorts of 4,000 lb capacity each. There will probably be plants in which this size unit would be too large and it is therefore planned to also build these units in sizes about one-half this capacity. This smaller size unit may result in a slightly higher labor cost as compared to the larger unit. However, the savings as compared with the operation of an equivalent retort plant would be in proportion.

It should be noted that the above savings are a comparison in the operating cost between the two types of equipment and that there would be additional savings in freight and treat-

ment charges where the equipment was installed at a galvanizing plant.

In presenting the foregoing figures I am aware that cost figures will vary from plant to plant and from month to month in a given plant. The figures given represent a pilot operation on full scale equipment insofar as the treatment of drosses in the resistor furnace is concerned. They do not, however, comprehend the over-all operation of a large plant.

The cost projected for a retort plant operation represents the best average that could be established on information supplied by operators of plants of this type.

A typical analysis on galvanizers dross is copper 0.01-0.04 pct, lead 0.2-1.0 pct, iron 2.9-3.5 pct, aluminum nil, zinc balance. The slab zinc produced from this type of material will run less than 0.02 pct iron and under Prime Western requirements in lead. The balance is zinc.

The furnace as designed for the distillation of galvanizers dross and other scrap zinc products has a relatively deep hearth so that the iron residue

may be accumulated for several days at which time it becomes necessary to stop charging and increase the temperature of the furnace to the melting point of the iron, that is, approximately 2750°F. This allows the residue to be tapped as a liquid containing approximately 8 pct zinc and the balance iron and lead. This residue can be sold to plants operating lead blast furnaces. However, there has been no credit given to the Wilkins-Poland furnace cost estimate for this item.

In the pilot plant operation galvanizers dross, scrap die castings and other scrap zinc, and the like, were re-distilled, producing slab zinc running between intermediate and high grade quality. This was accomplished by placing a small condenser in series with a regular condenser and returning an approximately 10 pct fraction condensed in the first condenser to the furnace. The principal reason for doing this was to obtain zinc extremely low in aluminum. The bulk of the material under these conditions was spectroscopically free from this element.

In distilling zinc from galvanizers

dross and other scrap zinc, the furnace can be operated so as to deliver a quite uniform amount of vapor to the condenser. This should prove very desirable in the production of zinc dust which is usually made from this source of zinc.

FURNACE IMPROVEMENTS

Improvements in construction have been made to the resistor furnace to reduce the heat losses, particularly at the top and side walls above the metal line. This was accomplished by more liberal use of lampblack insulation between the carbon and refractory lining on the side walls and by raising the insulators to a more remote location from the roof plates over the resistors. In consequence of this the weight of the roof and therefore the crane capacity to remove it when necessary was reduced from approximately 15 tons to approximately 5 tons. The power consumption on this later designed furnace is approximately 100 kw hr per ton less than on the original design.

Nonmagnetic steel has been inserted in the area influenced by the magnetic field of the lead-in terminals and the use of noninductive busses combined with the noninductive arrangement of the resistors results in a power factor of between 93 and 96 pct. This high power factor and steady load are of distinct advantage in that the lowest power rates are granted and the initial cost for electrical equipment is at a minimum.

Electric arc furnaces have been and are being used successfully for the melting of electrolytic copper cathodes and a further extension of this application is being made. The difference in the characteristics between the arc furnace and the Wilkins-Poland resistor furnace are such that a considera-

ble reduction in the installed KVA for any given capacity would result in a substantial saving. Increased efficiency due to the reduced radiation losses and extremely low replacement cost of the resistors as compared with arc electrodes makes the resistor furnace more economical than the arc furnace.

Special applications of the Wilkins-Poland furnace are being given consideration where the use of helium, argon, chlorine and nitrogen are to be used as atmospheres. Past experience with nitrogen as an atmosphere has shown that this type furnace can be made practically gas-tight and therefore it is practical to use these expensive gases where necessary.

There have been no changes in the dimensions or design of the condenser. However, one installation is being built in which a small primary condenser will be inserted between the furnace and the regular condenser. The purpose of this is to condense a 10 to 15 pct fraction of the zinc at this point in order to reduce the copper and lead in the approximate 85 pct remainder.

ECONOMICS

As stated in the previous publication the initial investment for building a plant to recover metallic zinc from scrap brass is appreciably less for this process and equipment than for any previous processes. The operating labor hours and other items as given in the previous publication are still applicable. However, the power required has been reduced approximately 100 kw hr per ton.

Summary

It has been shown that the high temperature electric resistor furnace distillation of zinc from secondary metals has proven, with further de-

velopment and use, to be superior in economic and metallurgical results to the older equipment and process.

The economics of melting miscellaneous scrap brass for the recovery of metallic zinc has been discussed and it has been shown that induction electric melting is more economical for this purpose than fuel fired furnaces.

The electric melting of electrolytic copper cathodes has been suggested as an application for the resistor furnace because it is believed to be more economical than the present 250 ton fuel fired reverberatory furnace practice for the production of tough pitch or oxygen free shapes. For this purpose the Wilkins-Poland resistor type furnace would be competitive in installation and operating costs.

Several new installations are in the engineering stage. These plants will be located both in this country and in Europe.

Although it is rather difficult to obtain prompt delivery of the transformers and other electrical equipment necessary for these furnaces at this time, the expansion in their use to date and the degree of interest as shown by inquiries for its application to other fields give every reason to believe that this new metallurgical furnace will find a wide and diversified use in the metallurgical field in the future.

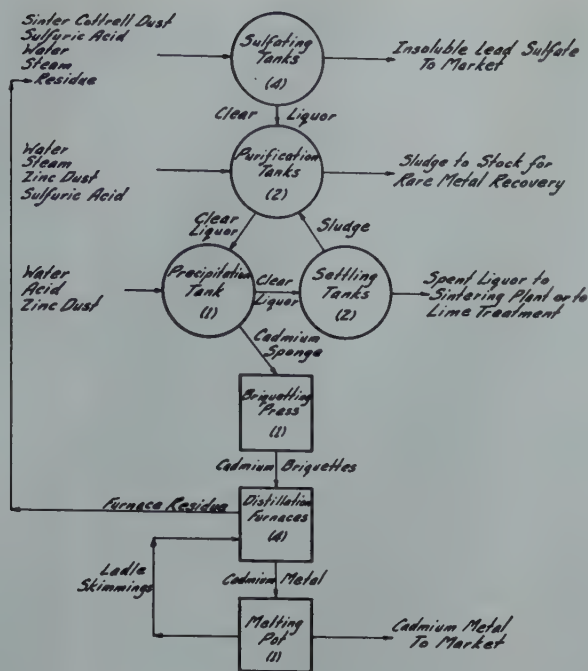

FIG 1—Flow sheet. Fire metallurgy of cadmium.

stacks. The bottoms of the tanks slope, 1 in. per ft, to 4 in. Everdur bronze gate valves. There are air, steam, water, acid and weak liquor connections to each tank.

In the treatment of dust, 3 to 4 ft of water, or weak cadmium wash liquor from a previous batch, is added to the sulphating tank. While this solution is being agitated a bucket of dust is placed on the dumping ring on the tank and the dust added slowly over a period of 15 to 30 min. An average bucket of Cottrell dust weighs 5 or 6 tons.

Acid sludge, when available, is added at this point to supply the necessary sulphuric acid for treatment. Care must be taken that too much sludge, and consequently too much sulphuric acid, is not added. All excess acid must later be neutralized with zinc dust. When no acid sludge is available 60° Baume sulphuric acid, from the Cadmium Plant storage tank, is used. The sulphating tank is then brought to a boil with steam to dissolve soluble material. Usually 4 to 6 hr of boiling and agitation are needed. The acidity is so adjusted that, upon final dilution with water, the solution will show approximately 1 pct acid. After dilution the steam is shut off and the lead sulphate allowed to settle. This settling period may be 6 to 8 hr.

To determine the acidity of the solution, a 10 ml sample of the liquor is titrated with sodium hydroxide using methyl orange as the indicator. It may be necessary to filter the sample before titration.

The purpose of the sulphating treatment is to put cadmium and zinc into solution and to convert lead to lead sulphate. The lead sulphate is practically insoluble and settles to the tank bottom leaving 7 or 8 ft of clear liquor above it. When the sample cup shows that the lead sulphate has settled sufficiently, a suction hose, from a lead LaBour pump, is dropped to within 6 in. of the mud level of the tank and the clear liquor decanted to one of the purification tanks. When the batch of clear liquor has been pumped out, the tank is ready for treatment of more dust. Usually two buckets of Cottrell dust and two tanks of acid sludge may be treated before it is necessary to remove accumulated lead sulphate. If no sludge is available, and sulphuric acid is being used in treatment, three buckets of dust may sometimes be treated before lead sulphate removal.

The above treatment and settling time will vary somewhat with the density, moisture content, chemical characteristics, and physical properties of the dust and sludge.

After the second or third batch of

clear liquor has been pumped to the purification tanks, the remaining lead sulphate is given a 1 pct sulphuric acid wash and several water washes. The acid wash is decanted to the purification tanks and treated as regular pregnant cadmium solution. The final washes of 2° Be' or less are decanted to storage for subsequent use as make-up water in the sulphating tanks. The accumulated lead sulphate is then pumped, as a slurry, to 25 × 50 ft concrete storage bins where it can again settle, and the water can be decanted off as necessary.

The lead sulphate is allowed to accumulate during the winter and in summer weather it is air-dried for shipment to lead smelters. This finished lead sulphate assays approximately 63 pct lead, 1 pct zinc, 0.2 pct cadmium, and may contain small amounts of silver. The use of acid sludge increases the lead content of the lead sulphate.

Purification

The two purification tanks are 8½ ft in diam and 15 ft deep. They are equipped with agitators, and individually ventilated. Each tank has a hinged cleanout door at the bottom which closes with a wheel clamp. These tanks

are agitated while the clear acid liquor from the sulphating tanks is being pumped into them. Zinc dust, or fine zinc skimmings, is added during agitation in sufficient amount to neutralize the solution. This addition of zinc precipitates part of the cadmium and nearly all impurities such as lead, tin, copper, silver, gallium, indium and germanium. It is very important that these purification tanks be well ventilated because of evolution of nascent hydrogen from the reaction of zinc and sulphuric acid.

The zinc dust or skimmings used as a precipitant is a mixture of metallic zinc and 5–10 pct zinc oxide. Normally 100 to 200 lb of zinc dust are needed to raise the hydrogen ion concentration of the batch to 5.5. The neutral point is checked with methyl red or preferably with Hydrion pH test paper. The tank is then agitated for several hours and allowed to settle. When the solution has settled a suction hose is dropped to within 6 in. of mud level and the clear liquor decanted to the precipitation tank by a LaBour pump. The purification tank is then ready for another batch of liquor from the sulphating tanks.

The liquor pumped to the purification tanks will have a Baume of 20 to 25° and, as stated before, will run about 1 pct acid. Higher acidity may cause a violent evolution of hydrogen and excessive foaming. The Baume must also be kept within reason, since usually the higher Baume solutions settle very slowly. When sufficient sludge has accumulated to prevent the tank from settling properly it is removed as discussed later under "Rare Metal Recovery."

Precipitation

The precipitation tank is identical with the two that are used for purification. The clear liquor from the purification tanks is pumped into this tank and enough sulphuric acid added to raise the acidity to 0.5 pct. Screened zinc dust or zinc skimmings is then added slowly to the agitated solution to precipitate cadmium sponge. Hydrogen is evolved by the reaction of zinc and sulphuric acid, therefore good ventilation is also necessary here. The solution must be kept acid, since a basic solution will precipitate a sponge which is not suitable for briquetting. A polished strip of metallic zinc is used to determine when all the cadmium has been precipitated. The zinc strip

will show no black stain when dipped in liquor from which all cadmium has been removed. The experienced operator can usually determine the end point visually as there is considerable gas evolved. At this point care must be taken to prevent excessive foaming or the tank may overflow.

When the end point is reached, the agitator is turned off and the grey metallic sponge settles quickly to the bottom of the tank. The clear liquor is then decanted to a settling tank. The sponge is not removed after each precipitation but is allowed to accumulate until 2000 to 3000 lb are in the tank. When ready for removal, the sponge is given a 1 pct cold acid wash followed by about six cold water washes. After pumping off the final water wash, the bottom door of the tank is opened and the sponge shoveled into barrels. The barrels of sponge are immediately covered with water to prevent oxidation. If allowed to stand in the air, the sponge becomes very hot and changes to the oxide. The sponge contains 90 to 95 pct cadmium, 1 to 2 pct zinc, 1 to 2 pct lead plus other impurities in small amounts. Most of these impurities are carried from the purification tank to the precipitation tank mechanically since the liquor does not always settle water clear. Also, pockets of gas in the mud on the tank bottom are released as the liquor above is removed and this disturbance in the tank causes some impurities to be carried over.

Following the precipitation tank are two settling tanks 10 ft in diam and 10 ft deep with agitators. The liquor pumped from the precipitation tank usually contains small amounts of cadmium which either are not precipitated or have gone back into solution. A small amount of zinc dust is added to the liquor pumped to the settling tank for removal of this last trace of cadmium and to neutralize any remaining acid. The tank is agitated until a test with tri-methyl-phenyl-ammonium iodide shows no cadmium in solution. The tank is allowed to settle clear.

This clear liquor is then pumped to a storage tank. The sponge which collects in these tanks is removed periodically and returned to the purification tanks, as it is not suitable for briquetting.

Part of this liquor is pumped to the sintering plant and serves as a wetting agent in the charge going to the sintering machines. Any excess wash liquor is treated with lime at the Cadmium Department and the precipitated zinc oxide and calcium sulphate, after being

filtered and dried, is sent to the sintering plant.

Briquetting

The cadmium sponge from the precipitating tank is briquetted in a Watson-Stillman press operated by an Oilgear hydraulic pump. This hydraulic press has a mold 6 in. in diam and 4 in. deep. The sponge is removed from the stock barrels and placed on the press table. To make a briquette, the mold is filled with sponge and pressure is applied. The upper plunger moves down and forces the pressure plate into the mold. Pressure is applied until the water and gas are squeezed out of the sponge and plunger stops moving—a matter of 5 to 10 sec. The upper plunger is then withdrawn and a lower plunger comes up, forcing the briquette from the mold. The briquettes are removed, as made, to a weighing scale, until 500 lb have been made. These 500 lb batches of briquettes are then returned to a barrel and again covered with water.

The finished briquette is 6 in. in diam and from $\frac{1}{2}$ to 1 in. thick. The total pressure applied is approximately 3500 psi. The water and fine particles of sponge, draining away from the press, are returned to the purification tank. This press will make from 1500 to 2000 lb of briquettes per 8 hr shift. The finished briquettes contain about 10 pct water. The briquettes apparently are not affected by being stocked under water, although when held for a considerable time hydrogen gas is slowly evolved.

Smelting

There are four tilting type furnaces for the distillation of the cadmium briquettes, each of which contains a Lava No. 40 graphite type retort and a cast iron condenser. They are fired by natural gas using a zero gas governor which gives a constant gas and air ratio. The distillation furnace is mounted with short axles on cast iron trunions and may be tilted by a hand wheel gear and pinion from a 30° distillation angle to a horizontal position for cleaning. The furnace is a cylindrical steel shell lined with firebrick and has two tangential burner ports diametrically opposite at the base of the shell to give the gas a swirling motion for uniform heating of the retort. The cast iron condenser is mounted on a four

wheeled iron carriage for convenient removal.

About an hour before charging a retort, 500 lb of briquettes are removed from under water and allowed to drain. The 500 lb charge is then placed in the hot retort. The cast iron condenser is placed in position over the retort and sealed with clay. In approximately one hour, steam from the charge is driven off and the metal begins to distill. The distilled cadmium is tapped, as often as necessary, into iron molds. Ordinarily it takes from 16 to 20 hr for a charge to work off. When the cadmium has distilled, the condenser is removed and the residue and slag scraped from the retort. The retort is then ready for recharging as before. An average 500 lb charge of briquettes will produce about 375 lb of metal and 35 lb of residue plus some condenser cleanings.

Cadmium residue, from the retorts, is crushed and accumulated for retreatment in the sulphating tanks with acid. The acid insoluble material is sent to the Waelz Oxide Plant for removal of residual cadmium. Any slag formed during smelting is also collected and sent to the Waelz Oxide Plant. Condenser cleanings are usually high in metallic cadmium and are recharged into a retort in separate batches. Fumes and dust from the furnaces are collected by hoods and recovered by a cyclone and Dracco dust catcher. This dust and fume are accumulated and acid treated along with residues.

The cadmium metal recovered from briquettes is ordinarily too high in lead for commercial use and must be redistilled. A 1000 lb charge of metal is placed in a relatively new retort and distilled as above, tapping metal from the condenser as often as necessary. A 1000 lb charge will normally produce

975 lb of metal ready for casting into commercial shapes.

Remelting

Redistilled cadmium is accumulated until a sufficient amount is on hand to fill an order or until it is convenient to recast it into commercial shapes. The cast iron melting pot is gas fired. It is hemispherical in shape, being approximately 4 ft in diam. A considerable amount of skimmings, consisting of a mixture of cadmium oxide and metal, collects on the pot of molten metal and must be skimmed off occasionally. These skimmings are accumulated for recharging into the cadmium furnaces. If the pot of molten metal is held at a high temperature too long, small amounts of zinc present will burn off and the cadmium metal will oxidize excessively. The temperature is kept slightly above the melting point of 320.9°C. The molten cadmium is ladled from the melting pot and cast into commercial shapes. The finished metal will run less than 0.1 pct zinc and less than 0.02 pct lead, plus spectrographic traces of several other elements.

Rare Metal Recovery

As stated under the heading of "Purification," the impurities removed from the cadmium liquor collect on the tank bottom until this bulk becomes so great that the solution in the tank will not settle properly. At this point, the accumulated sludge must be removed. This sludge contains cadmium, zinc, lead, tin, chromium, copper, germanium, indium, gallium and traces of

other elements below zinc in the Electromotive Series. Besides the cadmium and zinc, the only other elements being recovered from this sludge at present are the gallium, indium and germanium.

Previous to its removal, the sludge is given several acid washes to dissolve as much cadmium as possible. Before these washes are allowed to settle, they are made basic with a small amount of zinc dust to reprecipitate any rare metals which may have gone into solution. These decanted washes are treated in the precipitating tank to recover cadmium. The sludge remaining in the purification tank is then given a strong acid treatment to put as much material in solution as possible. After settling, the clear portion of this solution is decanted to the precipitating tank and treated with zinc dust. The precipitated sponge, containing rare metals, is removed, briquetted, and charged as usual into the cadmium furnace. The residue is saved for rare metal recovery. This sponge is occasionally too slimy to briquette and, in this case, is dried on a hot plate prior to treatment for rare metals. Such material may contain 4-7 pct germanium, 5-10 pct indium and less than 1 pct gallium.

The insoluble material remaining in the purification tank, after the strong acid treatment, is mainly lead sulphate and contains approximately 5 pct cadmium, 0.7 pct germanium, and 0.1 pct indium. This residue is pumped as a slurry to a storage bin for future treatment.

A separate set of tanks is used for rare metal recovery. Gallium, indium and germanium are currently being recovered and purified but it is beyond the scope of this paper to go into the methods of concentration and purification.

Technical Notes

On Feb. 16, 1948, the Board of Directors of AIME authorized the publishing of "Technical Notes" in METALS TECHNOLOGY (as of Jan. 1, 1949, *Transactions Section, JOURNAL OF METALS · TECHNOLOGY · PRACTICE*). The purpose is to provide *prompt* publication of *very short* items of the following general types:

1. Results of short investigations which do not warrant a paper.

2. The conclusions of extensive investigations of insufficient general

interest to justify a regular paper.

3. Conclusions arising in the course of an investigation, which, because of interest to others in the field, the author wishes to present prior to completion of the investigation.

4. Pertinent factual comment (not mere argument) on the subject matter of previous "Notes."

Such Notes will be subject to the approval of the Auxiliary and AIME Publications Committees, but can be handled more promptly than regular

papers because they need not be referred to readers. The recommended maximum length is 500 words; notes in excess of 1,000 words will not be considered for this type of publication. A graph or photograph may be included as part of the note when particularly illustrative. As with regular papers, contributions to the new section should be submitted to the Secretary of the AIME. Please furnish two copies each complete with illustrations.

The Statistical Nature of the Endurance Limit

[illegible]

J. T. RANSOM,* Junior Member, and R. F. MEHL,† Member, AIME

For many years the Metals Research Laboratory of Carnegie Institute of Technology has been concerned with the statistical nature of the engineering properties of steel from an experimental viewpoint, particularly those properties representing ductility.¹ In the past three years new work has been directed toward evaluating the statistical nature of the endurance properties. It has been shown that both the fracture curve and the endurance limit in fatigue are markedly statistical in nature.

The *S-N* curve (and the endurance limit) of ferrous materials is often determined with specimens which number as few as ten. The common procedure is to test the first specimen at a stress well above the expected endurance limit. Each succeeding specimen

is then tested at a progressively lower stress, until, after five or six tests, a specimen runs ten million or so cycles without failing. Two or three more specimens are then used to find the

Technical Note 15 E. Discussion of this note (2 copies) may be sent to *Transactions AIME* before August 1, 1949. Manuscript received February 14, 1949; revision received April 8, 1949.

† Head, Department of Metallurgical Engineering, and Director, Metals Research Laboratory, Carnegie Institute of Technology, Pittsburgh, Pa.

¹References are at the end of the note.

highest stress at which failure will not occur; the limiting stress determined in this way is called the endurance limit. It has now been found, however, that the variability in the fracture curve and in the endurance limit in heat-treated alloy forging steels is so great that $S-N$ curves must be drawn on the basis of distribution curves which can be appraised only by statistical methods.

Two methods have been adopted in this study: (1) straightforward statistical studies of cycles to fracture of a number of specimens at each of a series of stress levels, and (2) a new abbreviated statistical method, known as "staircase testing."² The latter consists in testing a series of specimens, one by one, with the test stress for any given specimen automatically

FIG 1—Results on a SAE 4340 steel.

determined by whether the preceding specimen failed or ran out unbroken through ten million cycles. The stress for the first specimen is chosen at a level where 50 pct failures would be expected if a large number of specimens were so tested, that is, at about one-half the tensile strength for steels. If the first specimen fails, the stress for the second specimen is decreased by one step, say 500 psi. If the first specimen "runs out" unbroken, the stress for the second specimen is raised by one step, and so on. The results on a SAE 4340 steel are plotted chronologically as X's (failures) or O's (non-failures), as in Fig 1. The X's and O's are then used to compute \bar{a} , the average endurance limit (the stress at which 50 pct of the specimens would fail and 50 pct run out), and σ , the standard deviation (if each of a very large number of specimens reveals its own exact endurance limit, the range $\bar{a} \pm 2\sigma$ would include 95 pct of these values). Calculation of the data in Fig 1 results in the prediction that the true scatter range in terms of $\pm 2\sigma$ extends from 40,460 to 52,080 psi.

This result is in conformity with findings of the usual statistical approach; 146 specimens were tested at

FIG 2—Value of $\pm 2\sigma$ for endurance limit.

stress levels distributed evenly over the 12,000 psi range indicated, and to this were added 64 specimens tested at stresses above the indicated average endurance limit. The value of $\pm 2\sigma$ for the endurance limit as calculated from these data gave 11,250 psi, Fig 2. Similar results were found for other forging steels in both the transverse and the longitudinal directions. It is interesting to note that groups of ten specimens chosen from the 210 samples in a manner to simulate the conventional testing procedure, but otherwise at random, provided eight *S-N* curves with points for each agreeing

with the drawn curve as well as on most published curves, but each curve showing wide divergence from one another, giving endurance limits ranging from 50,000 psi to 41,000 psi; such is the way that chance may operate, to the deception of the observer, in a statistical universe.

It is evident that estimates of the true endurance limit and of the fracture curve may be substantially in error when based on the small number of tests commonly employed. It appears that the fatigue properties of such steels can be appraised only on statistical grounds. Moreover, it appears that the endurance limit must be used in design in full recognition of its statistical nature; if design is based upon a stated stress level for the endurance limit, then, on principle, a fixed number of fatigue failures must be expected.

Temper brittleness refers to the loss in the notched-bar impact resistance encountered in most medium- or low-alloy steels when they are tempered within the temperature range of 700 to 1100°F or slowly cooled from a higher tempering temperature. Temper brittleness is important because it impairs the service properties of otherwise suitable steels over the range of hardnesses obtained at medium tempering temperatures and because it is impractical to cool pieces of large section rapidly enough from higher tempering temperatures to prevent temper brittleness.

The problem of temper brittleness has always been closely associated with ordnance manufacture because armor plate and gun steels require good shock resistance and are often heat treated in heavy section. However, it is now realized that many brittle failures in structural alloy steel parts are attributable to temper brittleness, and there is little question that it contributes to the low impact resistance of alloy steels used in the hot-rolled or normalized condition which are slowly cooled from the hot-rolling or normalizing temperature.

Recently Hollomon¹ has presented a comprehensive summary of the literature on the subject and an excellent description of the manner in which temper brittleness affects the notched-bar impact resistance and other mechanical properties of steel.

Carpenter and Robertson² have given a good analysis of the probable mechanism of temper brittleness, which is similar in many respects to the precipitation-hardening phenomenon. Fig 1 is their diagram illustrating the response to tempering of a susceptible steel. Three changes are recognized as the temperature of tempering a previously quenched steel is raised: (1) pre-

FIG 1—Effect of tempering on impact toughness.²

cipitation occurs more rapidly and to a greater extent and the notched-bar impact value falls to a minimum; (2) coalescence of the precipitated particles begins to be effective and the impact values for both rapidly cooled and slowly cooled specimens increase; (3) the precipitate goes back into solution at higher tempering temperatures and the impact values of specimens cooled rapidly enough to retain the solution increase, while reprecipitation occurs in slowly cooled specimens and their impact values decrease again. No change must proceed to completion before the following one begins and there is overlapping in temperature ranges.

Although there have been a large number of experimental investigations

of temper brittleness, insufficient evidence has been accumulated to permit definite identification of the precipitate which causes temper brittleness nor have the specific effects on it of various alloy elements and impurities in steel been definitely established. This lack of evidence is largely a result of the lack of a suitable measure for temper brittleness.

Temper brittleness is evidenced by an increase in the temperature of brittle failure of notched-bar impact specimens, but most of the data are in the form of an arbitrary susceptibility ratio of the room-temperature impact value for specimens quenched from a high tempering temper to that of similar specimens furnace cooled from the temper. It is obvious that this numerical ratio is dependent upon the type of specimen used and the specific conditions of testing rather than the characteristics of the steel.

In general, manganese, chromium, and nickel alloy steels are most susceptible to temper brittleness and molybdenum has been used to decrease

temper brittleness. The apparent effect of phosphorus in increasing temper brittleness has been attributed by Hollomon¹ to an increase in the temperature of brittle failure of nonembrittled steels of high phosphorus content which in many instances brings the divergence in the impact curves between embrittled and nonembrittled specimens closer to room temperature.

Various investigators have suggested that the temper-brittleness precipitate is a carbide, a nitride, a phosphide, or an oxide. Hollomon¹ states that the rate of diffusion of the responsible element is such that either nitrogen or carbon appears to be involved.

A recent study³ indicated that neither variations in the nitrogen content of susceptible steels, nor the addition of nitride stabilizing elements such as boron, aluminum, titanium, or zirconium have any appreciable influence on temper brittleness. It is possible to develop a form of temper brittleness in low-carbon Armco ingot iron which appears to be a result of iron carbide precipitate at the grain boundaries. However, when the carbon content is increased to about 0.15 pct and there are a large number of carbide particles throughout the grain, the grain boundary precipitate does not appear and unalloyed carbon steels do not seem to be noticeably temper brittle.

Copper and tin have lower solubility in ferrite at normal temperatures than in ferrite at higher temperatures and when present in sufficient amounts (much larger than normal) may produce a form of temper brittleness. Phosphorus has a solubility of about 1 pct in iron, and would, therefore, not

be expected to be a direct cause. Neither oxygen nor sulphur is believed to have the solubility characteristics in ferrite which would lead to temper brittleness, nor do the effects of other elements on temper brittleness fit in with their probable behavior.

This brief discussion indicates the need for further data on the specific influence of various elements on temper brittleness. The remainder of this paper discusses an investigation of the susceptibility to temper brittleness of a series of experimental low-alloy steels.

Materials and Test Procedures

Twenty experimental steels of the compositions indicated in Table 1 were melted by a standard induction furnace practice in a magnesium oxide crucible. Armco ingot iron was used as a base for all except the last two steels, for which electrolytic iron was used. One-tenth pct each of manganese and silicon was added as ferroalloys with the charge. Carbon and alloy elements were added after melt down. Final deoxidation was made 2 min. before pouring, using ferromanganese and ferrosilicon in all melts and aluminum in all but one. All melts were cast into 50-lb cast-iron ingot molds at a pouring temperature of 2950–3000°F as measured by an optical pyrometer.

The 50-lb ingots were forged to 1¼- × 4-in. billets and then rolled in the longitudinal direction to ½-in. plate at a finish rolling temperature of 1950°F. Impact bars were cut parallel to the rolling direction and ground to

½ in. square before heat treatment. After heat treatment, the bars were finish ground to 0.394 in. square, and a standard Charpy "V" notch was machined on a side perpendicular to the original plate surface. This notch orientation on rolled plate avoids split fractures and meaningless high impact values frequently encountered on specimens from forged bar or plate notched parallel to the rolled surface.

Heat treatments were as indicated in Table 2. The cooling rate on bars furnace cooled from the tempering temperature averaged 30°F per hr over the temperature range of 1100 to 700°F. Impact bars were broken in a standard Amsler impact testing machine with 103 ft lb initial energy in the hammer. Bars tested at subatmospheric temperatures were immersed in a dry ice-acetone bath for at least 15 min. before testing and broken within a few seconds of removal from the bath. Notched-bar impact values are given in Table 2. Rockwell A hardnesses taken on a ground surface of bars representing each heat treatment and Brinell equivalents obtained from the conversion tables supplied by the Wilson Instrument Co. are also given in Table 2.

Discussion of Results

The impact results given in Table 2 are limited to +75°F and –40°F. A steel which retains a relatively high impact value for the standard Charpy V-notch test at the latter temperature is generally regarded as sufficiently tough for most applications. However, it is not certain that a steel which had

equivalent values for furnace-cooled and water-quenched specimens at -40°F testing temperature would not show temper brittleness at lower testing temperatures.

Some measure of the temper brittleness of the various steels as tested at -40°F may be obtained by subtracting the average value for the furnace-cooled specimens from the average value for the water-quenched specimens. This is believed to give a better picture than the susceptibility ratio which is affected greatly by small differences in the value used for the denominator. The relative temper brittleness of the steels as indicated by this measure is shown in Table 3.

Tables 2 and 3 indicate trends for the influence of various addition elements on temper embrittlement of the base analysis (0.25 pct carbon, 0.20 pct manganese, 0.20 pct silicon, 0.02 pct sulphur, and 0.02 pct phosphorus) as described in the following paragraphs.

Approximately the same increase in hardenability, as calculated by the Grossmann method, should be obtained in the 1.0 pct manganese, 3.0 pct nickel, 0.75 pct chromium, and 0.5 pct molybdenum steels. Microscopic examination indicated that these steels transformed

almost completely to martensite during quenching as $\frac{1}{2}$ -in.-square bars. All of the steels but the 0.5 pct molybdenum one maintained high impact values at -40°F , and none of them showed temper brittleness on slow cooling from the temper.

A further increase in nickel content

to 5 pct lowered the critical temperature sufficiently that an intercritical structure with resultant low impact values was obtained for a 1200°F temper, but no temper brittleness was apparent when this steel was properly tempered at 1150°F . An increase of chromium content to 1.5 pct produced slight embrittlement, as did 0.5 pct carbon with 1 pct manganese, and 0.1 pct vanadium or titanium with 2 pct nickel.

Extreme temper embrittlement was produced by increasing the manganese content of the base analysis to 1.5 pct, by the combination of 1 pct manganese and 0.75 pct chromium, or by the addition of phosphorus to a 3 pct nickel steel.

Further experiments with the 1.0 pct manganese, 0.75 pct chromium-type steel were made to investigate the influence of deoxidation practice and molybdenum additions. Comparison of the steels, with and without aluminum addition austenitized at different temperatures to produce marked variation in austenitic grain size, showed no direct influences of these factors on temper embrittlement. Impact values for both water-quenched and furnace-cooled specimens were higher for the

FIG. 2—Comparative impact values for 0.02 pct P and 0.005 pct P steels quenched from 1625°F and tempered as indicated.

aluminum-killed steel than for the silicon-killed steel and higher for the silicon-killed steel austenitized at low temperature to give fine grain size.

The influence of molybdenum on temper brittleness is quite complex. An addition of about 0.20 pct molybdenum has a well-known beneficial effect in decreasing the apparent temper embrittlement of susceptible steels. Kishkin⁴ reported that additions of molybdenum or columbium, which were effective in preventing temper brittleness of susceptible steels quenched from 1690°F, were ineffective or even increased embrittlement if the steels were quenched from 2280–2370°F. This difference was attributed to solution of the molybdenum or columbium carbides in austenite at the higher, but not at the lower, quenching temperature. Pellini and Queneau⁵ reported that temper embrittlement developed in steels with high molybdenum content during extended holding at tempering temperatures as high as 1200°F.

The data of Maurer, Wilms, and Kiessler⁶ indicate that, if the molyb-

denum content is increased beyond a critical amount, the susceptibility to temper brittleness increases again. The results given in Tables 2 and 3 for molybdenum additions to the manganese-chromium steel indicate an optimum molybdenum addition which is less for a higher austenitizing temperature. However, these data on molybdenum additions, as well as the results obtained for 0.5 pct molybdenum, 1.0 pct molybdenum, 2.0 pct nickel-0.1 pct titanium, and 2.0 pct nickel-0.1 pct vanadium steels heat treated at 1625 and 1900°F austenitizing temperatures, and 1200 and 1250°F tempering temperatures, are quite inconclusive as far as establishing any clear picture of the role of these carbide-forming elements on temper embrittlement.

In view of the pronounced effect of an increase in phosphorus content on temper brittleness of the 3 pct nickel steel, two additional melts of the most susceptible steels (1.0 pct manganese, 0.75 pct chromium, and 1.5 pct man-

ganese) were made with an effort to obtain a minimum phosphorus content (0.005 pct phosphorus). A very marked decrease in the temper brittleness of these two steels as indicated by tests at -40°F (Tables 2 and 3) accompanied the decrease in phosphorus from 0.02 to 0.005 pct. In order to determine whether this could be an indirect effect of lowering the transition temperature for brittle failure of both water-quenched and furnace-cooled specimens, additional impact tests were made at -75 and -110°F testing temperatures.

The complete notched-bar impact data for normal and 0.005 pct phosphorus steels are given in Table 4 and plotted in Fig 2. Since lowering the phosphorus content has not improved the impact resistance of the specimens water quenched from the temper, the great improvement in the impact values for furnace-cooled specimens of the 0.005 pct phosphorus steel over those of the 0.02 pct phosphorus steel is attributed to a decrease in the susceptibility to temper embrittlement. As mentioned previously, these steels

(1) Water quenched
(2) Furnace cooled

were made by similar melting procedures and the only known difference, other than phosphorus content, is that electrolytic iron was used for melting stock of the low-phosphorus steel and ingot iron for the normal phosphorus steel.

These results indicate that phosphorus must have a much more important part in temper embrittlement than has been generally supposed. Several explanations are possible, but in view of the lack of fundamental data on the solubility of phosphorus in iron-carbon alloys, its influence on the solubility of carbon, and its reactions with other alloy elements in steel, no theory is advanced at this time.

Summary

Twenty experimental low-alloy steels were tested for temper embrittlement by comparing notched-bar impact values at +75 and -40°F testing temperature of specimens water quenched and furnace cooled from the tempering temperature.

For these conditions of testing, no embrittlement was apparent for nickel additions up to 5 pct to the base analy-

sis of 0.25 pct carbon, 0.20 pct manganese, 0.20 pct silicon, 0.02 pct phosphorus, and 0.02 pct sulphur. Chromium of 1.5 pct or either 0.1 pct vanadium or 0.1 pct titanium with 2 pct nickel gave slight embrittlement. Manganese of 1.5 pct or 1 pct manganese with 0.75 pct chromium produced extreme embrittlement. Deoxidation practice or grain size did not appear to have any direct influence on embrittlement. A moderate amount of molybdenum decreased embrittlement of the manganese-chromium steel. Increasing the phosphorus content of a 3 pct nickel steel produced temper brittleness, and decreasing the phosphorus content from 0.02 to 0.005 pct greatly decreased the embrittlement of the susceptible 1.5 pct manganese and 1.0 pct manganese-0.75 pct chromium steels.

Impact-resistance, transition-temperature curves for the latter steels indicate a real influence of small differences in phosphorus content on temper brittleness, but in the absence of fundamental data on the behavior of phosphorus in relation to carbon and alloy elements in steel, no theory of the mechanism of this influence is apparent.

Oriented Arrangements of Thin Aluminum Films on Ionic Substrates

T. N. RHODIN, JR.*

Introduction

There can be two types of films on solids, those which are stable in monolayers and those which tend to aggregate into three dimensional structures. A great number of metal films formed by condensation onto a solid base are unstable in the sense that they will aggregate into crystals providing the atoms possess sufficient surface mobility. The crystalline structure of the film is strongly influenced by the base in many systems and, in some cases, a single orientation prevails when the force fields around the atoms in the supporting crystal are sufficiently strong.¹ Relatively little is available in the literature about the nature of these forces and the role they play in promoting a preferred orientation of the atoms arriving at the substrate surface. An understanding of their periodicity and magnitude relative to the surface forces characteristic of the film itself should provide insight into the critical dependence of film orientation on the nature and temperature of the substrate.

In addition, this effect may be very useful in preparing samples for surface studies. The study of the physical and chemical characteristics of pure metal surfaces has been severely handicapped by the presence of strongly adherent foreign films. Furthermore, the randomness of the surface orientation has obscured interpretation of experimental results. Evaporation of metals in high vacuum onto carefully selected substrates under ideal conditions for preferred orientation appears suited to the preparation of flat, oxide-free, oriented films for surface reaction studies. Many factors influence their structure and some understanding of the mechanism of their formation is a necessary prerequisite for obtaining satisfactory surfaces for study. The dominant factors

Procedure

GENERAL ASSEMBLY

The system was enclosed in an 18 in. bell jar which rested on an L-shaped neoprene gasket on a ground steel plate as indicated in Fig 1. Rapid evacuation of the system to 10^{-6} mm mercury was facilitated by a 4 in. manifold, 2 in. packless valve, and an extra large diffusion pump. Suitable arrangement of valves on a secondary manifold readily permitted introduction of purified gases

into the chamber. Outgassing of the entire internal surface in a glow discharge was greatly expedited by a 5000 V copper cathode mounted at the top of the bell jar. The entire frame was carefully shock-mounted to isolate the microbalance from building vibration. The lead-ins for control and power were situated in the steel base. Pressures from 10 to 10^{-6} mm mercury could be measured and temperatures of the substrate and crucible could be independently controlled and measured. Atmosphere pressure seated the bell jar hard on the gasket when the latter was evacuated. When it was filled with dry nitrogen at one atmosphere it could be readily elevated out of reach.

FORMATION OF THE FILM

The film was produced by evaporating high purity (99.99 pct) aluminum from a microcrucible in a good vacuum (10^{-6} mm) and condensing it on an independently heated substrate. With

a suitable slit system a uniform, concentrated, direct molecular beam resulted. The arrangement of the source, slits, and substrate is indicated by items 2 and 1 in Fig 1.

The substrate (item 1) was mounted 25 mm above the source in a copper frame which held it in place against an externally heated copper block. In this manner the lower face was exposed to the beam and maintained at the desired temperature by heating from the upper face. The temperature was regulated to one percent by a proportionating potentiometer controller. The substrate consisted of a square plate of an ionic salt approximately 5 mm on the side and 1 mm thick. A freshly cleaved face was exposed just prior to a run. A thermocouple probe in contact with the lower face of the substrate indicated the film temperatures. Two additional platinum probes 2.0 mm apart were in contact with the surface. The appearance of the first few layers of the film was indicated by the sudden

decrease in resistance measured between the probes.

The source (item 2) of the beam was a small tantalum crucible located directly below the substrate. The microcrucible held a charge of 100 mgms. The inside diameter of the crucible was 3 mm but the beam was actually emitted through a 0.1 mm orifice in a tantalum cap placed over the top of the microcrucible. The cap prevented splattering and also promoted thermal equilibrium of the atoms before they were emitted. The charge was outgassed by prefusing *in situ* before evaporating during which time the substrate was protected by an externally manipulated shield.

The heating of the crucible was very satisfactorily effected by an arrangement for direct electron heating indicated in Fig 2. The crucible is shown with the lid off as item 1. Electrons emitted from an incandescent 30 mil tungsten filament (item 2) around the crucible are accelerated by a positive

potential towards it. A tantalum shield (item 3) around the assembly reduced heat losses and another tantalum lid (item 4) shielded the substrate from direct exposure to the filament. The temperature of the microcrucible could be accurately adjusted and maintained at any temperature up to 1500°C within 2–3 pct by regulating the filament emission and the accelerating potential. This high fidelity temperature control is necessary in the determina-

tion of the substrate temperature condensation-pressure relationship for various substrates. The substrate was tied in at the same potential as the crucible to eliminate the possibility that metal ions formed in or around the crucible may be spuriously accelerated towards the substrate.

The critical vapor pressure for condensation on a given substrate at a given temperature could be determined as follows: In this measurement

the crucible temperature was slowly increased until the rate of evaporation of the aluminum was just enough to cause condensation on the substrate for a given base temperature. The rapid decrease in the film resistance between the probes was used to indicate the formation of the initial layer. The process was reversible, that is, a small increase in base temperature for a critical pressure caused the film to evaporate. The microcrucible could be readily removed

FIG 5—X ray pattern.

from the crucible electrode (item 6) for replacement and the position could be lined up easily by adjusting the eccentric at the base. The crucible temperature was measured by a chromel-alumel thermocouple mounted in the bottom.

DETERMINATION OF FILM THICKNESS

The condensation rate for a given crucible and substrate temperature was determined by weighing *in situ* a thin glass slide hanging on a quartz fibre over the molecular beam as indicated in Fig 3. A sensitive quartz torsion microbalance facilitated accurate and quick measurements in vacuum. The torsion fibre was rotated by magnetic coupling through the glass wall. The sensitivity of the weighing was 10^{-6} gm with a 23 mu. quartz torsion fibre (item 5). The thickness corresponding to weight increments was calculated for a constant area assuming the film to be flat and continuous and the film density to be comparable to the mass density. A microgram corresponded to a hundred angstroms thick layer of aluminum for the film area used. The condensation rates for various substrate and crucible temperatures were calibrated in this manner.

EXAMINATION OF THE FILM

Metallography

Upon completion of the run the substrate was cooled *in situ* and removed for examination. Reflectivity of the surface varied from very mirror-like to cloudy as the film thickness and substrate temperature increased. Metallographic examination of the samples was considerably hampered by their fragility. In the cases where it was possible to observe grains without destroying the film the average grain size was 2000 to

5000 Å for a film of the same thickness.

X ray Diffraction

The structure was determined with X ray diffraction using a surface reflection pin-hole technique in a vacuum camera as indicated in Fig 4. A Picker-Waite diffraction unit was used with a water-cooled chromium target. The exposure time varied from 2 to 15 hr for film thicknesses from 5000 to 500 Å with an accelerating potential of 50 kv and a space current of 10 milliamp. The sample (item 6) was anchored flat on the turntable (item 7) and rotated around an axis (item 19) normal to the surface of the sample. The axis of rotation was inclined away from the incident beam an amount corresponding to the Bragg angle for reflection from the plane of preferred orientation. The camera was particularly designed to suit the geometry and orientation unique to the samples studied. The simplicity of the film patterns indicated in Fig 5a and 5b clearly shows the advantage obtained. Preferred orientation is characterized by segmentation of the lines into local marks as shown by the heavy marks of 5° length on the dashed reflection lines in Fig 5b. The vertical distance from the center line measures the orientation azimuths characteristic of a preferred orientation. The value of the orientation azimuth (ϕ) can be calculated for any preferred orientation,^{1a}

$$\cos \rho = \cos \beta \sin \theta + \sin \beta \cos \theta \cos \phi \quad [1]$$

ρ = angle between oriented plane and reflecting plane.
 β = angle between normal to oriented plane and incident beam.
 θ = Bragg angle for reflection from reflecting plane.
 ϕ = orientation azimuth for oriented plane.

The values of ϕ calculated for reflection of K_α and K_β chromium radiation from the (111), (200), (220) and (311) planes of aluminum for (111), (100) or (110) orientation are listed in Table 1. The kind of orientation can be readily determined from the pattern defined by the characteristic values of ϕ . A semi-quantitative value for the degree of orientation with a maximum error of 10 pct in this determination can be obtained by measuring the opaqueness of the spot relative to the integrated opaqueness of the whole line with a Leeds and Northrup recording microphotometer. The error is introduced by the assumption that the intensity at any one spot on the film is linearly proportional to the amount of radiation reflected to that point and the dependence is the same for all azimuth angles.

Orientation Results

GENERAL

A quantitative dependence of degree of preferred orientation on film thickness and substrate temperatures was found over a considerable range of thickness and temperature for eleven aluminum-substrate pairs. It was necessary, however, to make a preliminary evaluation of four other factors sufficiently well so as to minimize their influence. The pertinent results of the preliminary survey are herewith presented in condensed form as a background against which the significance of the quantitative aspects can be considered more intelligently.

Film Growth Rate

Foremost is the important influence of film growth rate on structure. Since the experimental system was not propitiously suited for studying this aspect it was maintained at a constant value in all experiments. The evaporation

FIG 6—Orientation and base temperature (1).

FIG 7—Orientation and film thickness.

rate was adjusted for each substrate temperature corresponding to an effective film growth rate of ten to thirty monolayers of aluminum per second. In the case of the binding energy determinations, however, the film growth rate was not controlled since it was desired only to determine the condition for minimum condensation.

Heat Treatment

Heat treating of the substrates with or without adherent metal film caused no striking change in the resulting orientation. The films were therefore usually kept at constant temperature during formation and then permitted to cool by radiation in a vacuum. Annealing a randomly oriented film at elevated temperatures (up to 600°C) in helium resulted only in grain growth. Likewise oriented structures were not markedly altered by annealing under similar conditions. This temperature stability of the structures is in contrast to the temperature sensitive orientations of thinner aluminum films (ca. 400 Å) previously reported.²

Atmosphere Effects

The influence of gases present even at 10^{-6} mm pressure was also considered. The pressure of purified quantities of helium, oxygen, nitrogen and hydrogen at low pressures (10^{-4} mm) decreased the orientation to a relatively small extent. The effect was not unique to any one gas or substrate and appeared solely to hamper the steady evolution of aluminum vapor. In no case was a gas such as helium observed to improve the film orienta-

FIG 8—Orientation and base temperature (2).

tion as reported by others for thinner films.³

Substrate Condition

The contamination of the substrate surface itself by the gases previously listed was not considered to be critical. Oriented films could be formed on freshly cleaved rock salt which had been preheated in oxygen and hydrogen atmospheres. In all cases, however, the cleanliness of the substrate was a critical requirement and best results were

always obtained with freshly cleaved ionic surfaces whose lattices had an arrangement of ions, the geometry and dimensions of which showed a certain correlation to that of aluminum. The limited number of such salts emphasized the preparation of oriented substrates by other means. Even after repeated polishing, etching, and annealing, use of NaCl and LiF surfaces obtained in this manner was only moderately successful. Successful techniques for exposing any desired sub-

strate orientation in a suitably clean and flat condition would be most useful for future studies.

SPECIFIC FACTORS

Film Thickness

Initial studies made it evident that degree of orientation was very thickness dependent for all film-substrate pairs. This characteristic will be described first since it depended only on temperature and film thickness and was general to all substrates. The percent orientation for films on the (100) face of rock salt for various thicknesses and base temperatures are plotted in Fig 6 as an illustration. An exponential dependence of orientation on film thickness was observed, and the data plotted in Fig 7 indicate a typical case. It is interesting to note that a critical film thickness for perfect orientation at each temperature is suggested by extrapolation of the straight line to small film thicknesses. A striking temperature dependence is also indicated by the distinctly small slope of curve 2 compared to curve 3 in Fig 7. The validity of a strong base temperature-dependence for maximum orientation is also indicated in Fig 8 for a variety of film-substrate pairs. Discussion of the temperature dependence is, however, temporarily postponed until right after the discussion of the thickness effect.

The thickness dependence may mean that the oriented arrangement is constant at all points in the film and merely decreases as the film thickens. It seems more reasonable to assume that the orientation is strongly dependent on the substrate and produces an orientation large at the inner film surface and decreasing towards the outer film surface. The latter possibility is in agreement with the surface reflection characteristics of X rays. In this case a disproportionately large fraction of the radiation producing the pin-hole pattern is reflected from the outer planes of the film. A quantitative illustration of this can be presented by calculating the intensity of radiation reflected from successive layers of metal atoms as follows.⁴ The intensity (I_t) reflected from a thickness (t) relative to the intensity (I_d) reflected from an infinitely thick film can be expressed:

$$\frac{I_t}{I_d} = \frac{\int_0^t I_2 dt}{\int_0^\infty I_2 dt} \quad [2]$$

$$\text{where, } I_2 = kI_0 e^{-4\left(\frac{\mu}{\rho}\right)\rho\left(\frac{td}{\lambda}\right)} \quad [3]$$

Neglecting the scattering of the ray after it has emerged from the sample, I_2 is the final intensity, I_1 the intensity, upon reflection from a diffraction volume element at a depth, (t), below the surface, and I_0 is the incident intensity before entering the sample. The term $\left(\frac{4td}{\lambda}\right)$ is a linear expression of the total distance traveled in the sample when the ray penetrates a depth, (t), and undergoes a Bragg angle reflection. The other symbols are,

k = efficiency constant \leq unity

I_0 = initial intensity of incident beam

$\left(\frac{\mu}{\rho}\right)$ = mass absorption coefficient

ρ = film density

d = interplanar distance of oriented planes

t = film thickness penetrated

λ = wavelength of X ray radiation.

Values of $\frac{I_t}{I_d}$ for a limiting thickness of $5 \times 10^5 \text{ \AA}$ have been calculated from Eq 2 for successive depths of penetration into the sample. The amount of radiation from each layer characterizes the degree of orientation in that layer and the over-all variation of apparent orientation with film thickness indicates the decrease of average orientation with increasing film thickness. The calculations were made for the K_α radiation from a chromium target diffracted by the (100) oriented planes of aluminum. The results in Table 4 are presented: Column 1, depth of penetration (\AA); Column 2, thickness penetrated relative to limiting thickness, and Column 3, the corresponding percent intensity for that thickness penetrated over the total radiation recorded on the film.

Although the pin-hole pattern is an integrated effect of orientation through the entire layer, it is obvious that the pattern is a weighted average heavily in favor of the extreme surface. For example, with a chromium target twice as much radiation is reflected from the outer half thickness than from the inner half thickness of an aluminum film 5000 \AA thick. Hence, in the film thickness study the orientation of the outer surface was essentially observed. The orientation is greatest in the region nearest to the substrate-film interface.

Substrate Temperature

A base temperature dependence in which orientation of the film increased rapidly at some characteristic tem-

perature for each substrate illustrated in Fig 8 was typical of all substrates. The less the maximum orientation, however, the smaller the dependence on the characteristic temperature. This is illustrated by the contrast in the curves for (100) orientation on rock salt and glass. The temperature dependence may mean that the metal atoms must possess a minimum kinetic energy corresponding to the observed temperature for maximum orientation for them to take up the preferred positions suggested by the substrate. The transition of a (110) orientation of the film on mica at low temperatures to a (111) orientation at higher temperatures indicates that a higher minimum mobility is required for formation of the second configuration. In all cases the rate at which orientation increased with base temperature as well as the maximum value it approached was typical of the substrate. It indicates that production of ordered arrangements is governed not only by the interaction of the substrate and metal but by a relatively slow temperature dependent surface diffusion process as well. Calculation of activation energies for orientation seems premature until the mechanism of arrangement is better defined. The characteristic values of base temperature and maximum observed orientation are plotted in Fig 8 for rock salt, mica, and glass, and listed for eleven substrates in columns 2 and 4 of Table 2.

Experimental data for mica in the temperature region intermediate between the (110) and (111) orientations were inconclusive. It is noteworthy that the most oriented configurations corresponded to the higher temperatures. This characteristic is a general one for all the substrates studied. It is illustrated by the dashed curve in Fig 8 in which the orientation temperature as abscissa is plotted against the substrate binding energy as ordinate on the right. The substrate binding energy, heretofore undefined, is described in a subsequent section and shown to be proportional to the percent of the observed film orientation.

Nature of Substrate

From the facts presented so far it seems clear that the nature and degree of the observed orientation was critically dependent on the substrate. This dependence held in general for all the substrates studied. In every case there was a correlation of some kind between

FIG 9a—Aluminum-glass random orientation (10,000 Å).
 FIG 9b—Aluminum—(100) sodium chloride 80 pct (100) orientation (1200 Å).
 FIG 9c—Aluminum—(111) mica 87 pct (111) orientation (1300 Å).
 FIG 9d—Aluminum-glass 10 pct (100) orientation (1000 Å).

the geometry and dimensions of the underlying lattice and that plane of aluminum preferentially oriented parallel to it. For example, the (100) face of aluminum was the only orientation observed on the (100) face of the alkali halide substrates. Similarly the (111) planes of aluminum tended to be preferentially oriented parallel to substrates with hexagonal cleavage or hexagonal-polished faces, providing the base temperature and film thickness were favorable. In other cases (110) orientation was observed to occur on (110) oriented substrates. This is not a general effect, however, since cases occur where substrates stabilize preferred film orientations other than their

own, but in most cases that orientation of aluminum occurred for which the geometry and spacing of the metal atoms yielded the best fit on the substrate. The data are summarized in

columns 1, 2, 3, 4 of Table 2 in order of decreasing orientation. The direction of orientation in the film listed in the third column is the same as that of the substrate for the first seven items. A small

FIG 10—Aluminum unit cell.

FIG 11—Alkali halide unit cell.

orientation was observed on glass which, of course, possesses no definable surface arrangement. The small degree of orientation on fluorite was barely measurable. The (111) orientation on zinc blende and sodalite was also very small. The last two substrates possess cubic lattices with good (110) cleavage faces and are examples of film orientation differing from that of the substrate. Some typical surface reflection X ray film patterns are illustrated in Fig 4. The interpretation is handicapped by the poor contrast of the aluminum lines,

the strong and complex pattern caused by reflection from the substrate, and the poor reproduction, but the over-all pattern analysis is quantitatively unique for each orientation. Continuous reflection from all the low indices reflection planes indicate complete randomness in Fig 9a. The sharply defined orientation of a (100) aluminum film on rock salt is illustrated in Fig 9b. Fig 9c is greatly complicated by the mica pattern but arrows indicate the discrete aluminum reflections corresponding to (111) orienta-

tion. A poorly oriented film on glass tending towards (100) orientation is included for comparison (Fig 9d).

Discussion of Results

GEOMETRIC CONSIDERATIONS

The good correlation between substrate and film orientation is in accord with the excellent matching between the oriented aluminum plane and the geometry and dimensions of the surface lattice upon which it forms. Similar results have been reported for thinner films.⁵ The striking geometric kinship between the three low indices planar arrangements: (100), (110), (111), of aluminum in Fig 10 and the geometry of the corresponding planes in sodium chloride and lithium fluoride in Fig 11 suggests that such correspondence between film and substrate promotes a related orientation in the former. This hypothesis is suggested by the table of lattice distances summarized in Fig 11. They agree within a few percent in each case except for the (111) sodium chloride face, for which the lattice spacing is 40 pct greater than the corresponding spacing in the (111) aluminum plane. It is doubtful whether this correlation is generally essential for substrate-metal interaction but it is significant that no (111) orientation of aluminum was ever observed on a (111) sodium chloride surface. Corresponding orientations were observed in every other case.

Substrates with hexagonal cleavage faces of atomic dimensions corresponding to the (111) face of aluminum yielded (111) oriented aluminum films. The fairly complicated surface structure of mica accommodated (110) arrangement of aluminum as well. The arrangement of the atoms in the hexagonal cleavage faces of mica, calcite and fluorite are drawn to scale in Fig 12. The matching of lattice distances was poorer than for the cubic face cleavage substrates and the observed degree of orientation was also correspondingly poorer with the exception of mica. The (110) cleavage faces of cubic zinc blende and sodalite are not indicated but the matching was relatively poor for both substrates and they were unsatisfactory as (110) directing surfaces.

In all cases studied the nature and degree of the observed film orientation bore a close relationship to the geometry and dimensions of the underlying substrate. It appears that directing forces are geometrically distributed on

the substrate surfaces in close correspondence to the atomic distribution in the substrate plane. An interpretation based on this approach will be discussed in the next section.

CHARACTERIZATION OF SUBSTRATE

In an effort to characterize the substrates an effect, discovered by Wood⁶ and studied by Estermann,⁷ was used in a modified form. When a beam of metal vapor is directed at a heated substrate, condensation will occur if the pressure is sufficiently high or the substrate temperature sufficiently low. Whether most of the atoms bounce off the surface losing none or relatively little of their kinetic energy or whether they are accommodated on the surface depends on the relative values of the aforementioned variables plus a third, the attraction of the substrate for the metal atoms. Since the relationship between these factors can be quantitatively expressed, the attraction of the substrate may be determined providing the corresponding pressures and base temperatures can be measured. This pressure-temperature dependence was determined as follows for all the substrate-metal pairs at those substrate temperatures at which maximum orientation was known to occur in each case. The substrate temperature was measured with a thermocouple probe on the surface. The metal pressure was not measured directly but calculated from the crucible temperature using the free energy of vaporization values for aluminum.⁸ The minimum vapor pressure was accurately determined for each base temperature at which condensation of the first layers took place. The formation of the first layer was indicated by measuring the sudden drop in film resistance between two probes on the surface. The corresponding values of pressure and base temperature for a group of typical runs are plotted in Fig 13. The pressure-temperature relationship can be expressed,

$$p = a_1 e^{-A/RT} \tag{4}$$

- where,
- p = pressure of metal vapor
- a_1 = constant, insensitive to temperature
- T = absolute temperature of the substrate
- A = an energy term, characteristic of the film and the substrate.
- The values of a_1 could be evaluated from the intercept on the pressure axis of the curves plotted in Fig 13. It is

FIG 12—Hexagonal substrates.

FIG 13—Condensation temperature and pressure.

insensitive to the nature of the substrate and to the base temperature for the conditions observed. Hence, it was of little use for characterizing the substrates on a relative basis. It, however, includes at least three significant terms describing: (1) geometry of the system; (2) size of the condensing particles; (3) a linear temperature correction. Hence,

an interpretation of the mechanism of condensation would eventually require an analysis of a_1 into its component terms. The values of A could be readily interpolated from the slopes of the straight lines plotted in Fig 13. Some typical values are listed there in order of decreasing magnitude. Correspond-

FIG 14—Orientation and substrate.

ing values of temperature, pressure, and A are more completely listed in columns 2, 5 and 6 of Table 2.

A definite trend of A in Table 2 from 42 kc per m to 20 kc per m is evident. This trend corresponds to decreasing observed orientation. It is significant that the values of A are smallest for the ionic substrates at the end of the table for which the orientation was poorer. The smaller surface free energy of the (111) arrangement corresponds to the observation that the A values for (111) substrate-film orientations are somewhat greater than those for (110) and (100) orientations for each substrate-metal pair.

An interpretation of A as describing the heat of condensation of the first layer of metal atoms on the substrate is indicated by the temperature dependence relationship established by the straight lines in Fig 13, and by the empirical findings of Wood and Estermann. A theoretical analysis of their work by Semenoff⁹ applied to these results indicates that

$$A = E + \Delta \quad [5]$$

where,

E = the adhesive energy of binding of the metal and substrate

Δ = the energy of binding of the aluminum atoms in the first layer, that is, the surface energy characteristic of the metal film itself.

If the first term is large the substrate is likely to influence strongly the formation and arrangement of the atoms in the first layer providing the atoms pos-

sess sufficient mobility to assume those positions on the surface of lowest potential energy. If it is small, relative to the second term, that is the adhesive forces between metal and substrate are negligible compared to the cohesive binding between metal atoms, the film formation will be relatively independent of the substrate and, should any orientation occur, it will be that arrangement for which the surface free energy is smallest. Formation of an oriented first layer under the first condition would facilitate the occurrence of the same orientation for subsequent layers. The degree of observed orientation should increase with the value of E providing other factors are also favorable, that is, mobile atoms and relatively thin films. Formation of an oriented layer under the second condition may also occur but the degree of orientation will likely be considerably less. It is noteworthy that the values of A varied from 42 kc per m for aluminum on mica to 15 kc per m for aluminum on glass (column 6, Table 2). In the latter case one might consider the interaction between the glass and the metal to exert a relatively small influence on the film structure and the measured heat of condensation to correspond mainly to the cohesive forces in the (100) plane of aluminum. Since there are about one-third the number of bonds in this configuration compared to that of massive aluminum, the surface energy can be roughly approximated to be one-third of the molar heat of vaporization or 22 kc per m. For this

crude approximation the order of magnitude agrees with the experimentally determined value measured on an amorphous substance like glass. Neglecting the entropy correction, the substrate binding energy for the other substrate-metal pairs may be similarly approximated by subtracting an energy, Δ , corresponding to the cohesive binding energy of the film, from A , the total energy of condensation. In view of the assumptions involved the values obtained are speculative but the resulting values (E) listed in column 8 of Table 2 are of the right order of magnitude. These approximations compare favorably with values calculated on the same basis as Van der Waals interaction. The trend of the experimental values of E is in qualitative accord with the trend of observed orientations for each metal-substrate pair. This is indicated by the data on the maximum orientation and the substrate binding energies listed in columns 4 and 8 in Table 2. The correlation is also evident in Fig 14 in which the maximum observed orientation is plotted as ordinate against the substrate binding energy as abscissa. The calculated values, included for comparison, are now discussed.

VAN DER WAALS INTERACTION

Understanding of the binding between a metal and an ionic surface would provide considerable insight as to the nature of the metal-substrate interaction. A rigorous attempt to define the binding is well beyond the scope

of this paper, but some speculation in this direction seems justified. The characteristics of the binding, namely its relative magnitude and non-specificity, suggest the validity of an approach based on Van der Waals interaction between the first layer of metal and the substrate. An analysis similar to a certain extent to the calculation of heats of adsorption of gases physically adsorbed on ionic surfaces near the boiling point of the gas seems justified. It is obvious that the chief distinguishing characteristic between metal and physically adsorbed gas films, other than the different temperature range in which they form is the marked importance of the cohesive forces in the former case. It is conceivable nevertheless that a strong periodicity in the potential energy surface of the substrate towards the metal atom may be sufficient to start the condensation in a favored direction. The energy of Van der Waals binding of aluminum on each of the substrates was calculated on this basis.

The Van der Waals interaction between non-polar molecules has three important constituent parts: (1) the attraction between fluctuating dipole and induced dipole (dispersion effect), varying inversely as the sixth power of the distance; (2) the attraction between fluctuating quadruple and induced dipole varying inversely as the eighth power of the distance; and (3) the repulsion energy decreasing exponentially with the distance. A fourth constituent part is unique to ionic surfaces: the so-called influence effect. The latter is due to the fact that the charged ions of the substrate induce a dipole moment in the metal atom, which results in an attraction between the ions and the induced dipole. At the equilibrium distances characteristic of the metal films, the first of the four terms is by far the most important. The calculations were made on an approach similar to Orr¹⁰ in which he calculated heats of physical adsorption of argon on potassium chloride.

The dispersion effect was introduced by London¹¹ in the calculation of heats of adsorption. The dispersion potential ϕ , between an atom of metal and an ion of the substrate can be written

$$\phi = -\frac{C}{r^6} \quad [6]$$

where r is the equilibrium distance and C , the dispersion constant, is given by

$$C = \frac{3}{2} \alpha \alpha' \frac{JJ'}{J + J'} \quad [7]$$

where

α = polarizability of the metal

α' = polarizability of the ion

J = characteristic energy of the metal

J' = characteristic energy of the ion

The interaction between an atom and the entire surface of the substrate can be very simply calculated if one assumes that the distance between atom and ion is not smaller than the distance between ions. In this case the summation over the ions of the substrate can be replaced by an integration. In the case of alkali halide substrates this approximation will yield values that are too low by 25 to 30 pct. For the mutual dispersion energy of an infinitely large surface and an isolated atom,

$$\phi = -\int \frac{C}{r^6} N dv = -\frac{N\pi C}{6r^3} \quad [8]$$

where N = number of ions per cc, and

dv is the volume element. Substituting Eq 6 for the dispersion constant

$$\phi = -\frac{N\pi \alpha \alpha'}{4 r^3} \frac{JJ'}{J + J'} \quad [9]$$

An exact evaluation from Eq 8 is not possible because some of the experimental data are missing, particularly the value of J for aluminum. Nevertheless, to show the order of magnitude calculations were made using the first ionization potential. The value of N for the substrates other than the alkali halides was calculated from the density. The distance, r , between an ion and an aluminum atom was assumed to be made up of two parts after London.¹²

$$r = \frac{d_1}{2} + \frac{d_2}{2} \quad [10]$$

For $d_1/2$, half the distance between ions in the substrate was used and for $d_2/2$, half the interplanar distance for that plane of aluminum observed to be

FIG 15—Potential energy surface aluminum on (100) sodium chloride.

preferentially oriented. The identity and geometry of the important ions in the substrate were not always definitely established and a choice had to be made in some cases. The ion was chosen whose arrangement on the surface best fitted the observed aluminum orientation. For example, the oxygen ions were chosen, instead of the silicon ions, in mica. The calculated binding energy for both is listed in Table 3 for comparison. The atomic polarizabilities were taken from Van Vleck¹³ if possible, or calculated,

$$\alpha = \frac{e^2}{4\pi^2 m \omega^2} \quad [11]$$

where ω is the characteristic frequency of the atom and the other symbols have the customary significance. The polarizability and characteristic energies for the ions of the alkali halides were taken from Mayer's¹⁴ analytical treatment of the lattice energy characteristics of alkali halides. The validity of the physical constants in this case warranted more extended consideration. A potential energy surface for the system (100) aluminum-sodium chloride was constructed after Orr.¹⁵ It is schematically represented in Fig 15. The potential hole in the center represents a position of the aluminum in which the potential energy is 7 kc per m lower than a position over the cation. The position over the anion corresponds to the highest potential energy on the surface. For this system it is evident that the central site is relatively large but is deeper by 7 kc per m than the next most favorable site and corresponds to a binding energy of approximately 18 kc per m. It is noteworthy that the atoms of the (100) aluminum plane could be laid over the grid formed by the potential energy holes with negligible distortion. The calculations are summarized in Table 3, in which the atom positions, the ionic polarizabilities, the characteristic energies, the dispersion constants and the calculated substrate binding energies are tabulated for thirteen substrate-metal pairs in columns 1 to 7.

Considering the approximations involved in the theory and the uncertainties in the assumed values of J and r

Table 4 . . . Disproportionate Variation of Intensity of Diffracted X ray Radiation with Depth of Penetration

| (1) | (2) | (3) |
|-----------------|---------------------|-----------------------|
| t (Å) | Pct $\frac{I}{I_d}$ | Pct $\frac{I_t}{I_d}$ |
| 5×10^2 | 1 | 9 |
| 5×10^3 | 6 | 24 |
| 5×10^4 | 25 | 53 |
| 1×10^5 | 50 | 76 |
| 5×10^5 | 100 | 100 |

one cannot expect, in general, more than an agreement in the order of magnitude between calculated and experimental values. The calculated values (E_c) in column 9, Table 2, should be evaluated on that basis. It is considered fortuitous that the calculated values other than for the alkali halides agree as well as they do with the experimental values (column 8). It is significant, however, that the highest values correspond to the substrates upon which the best oriented aluminum films were formed and that the trend definitely agrees with that characteristic of the percent orientation for all eleven substrates and with the indirectly determined substrate binding energies.

It is evident that the periodicity of the potential energy surface of the substrate-atom pair is a very important factor in defining the arrangement of the metal atoms.

Conclusion

The structure of thin aluminum films condensed in vacuum on clean ionic substrates is strongly influenced by the nature, geometry and temperature of the ions in the base. The degree of orientation of the film with respect to the base can be semiquantitatively correlated with a binding energy characteristic of the substrate. The values of the substrate binding energy are of the same order of magnitude as Van der Waals binding between a single atom and an infinite ionic surface. The characteristics of the film structures show this method to be effective for the preparation of oxide-free oriented alu-

minum surfaces for studying surface reactions.

Acknowledgments

The writer is indebted to many of the research faculty for opportunities to discuss the subject and particularly to Professors Charles Barrett, Clarence Zener and Cyril Smith of the Institute for the Study of Metals and to Professor Joseph Mayer of the Institute for Nuclear Studies. In addition, all the structure determinations were made in Professor Barrett's X ray Diffraction Laboratory with the assistance of Messrs. Donald Clifton and James Hess, whose cooperation is gratefully acknowledged.

P-type and N-type Silicon and the Formation of the Photovoltaic Barrier in Silicon Ingots

J. H. SCAFF,* Member, H. C. THEUERER* and E. E. SCHUMACHER,* Member AIME

The microwave region of the radio spectrum was effectively utilized in radar designs during the recent war and it has become of increasing interest in the field of communications. Work in this field has led to an important use for silicon—that of the point contact rectifiers† in the frequency converter of microwave (radar or radio) receivers—and has stimulated considerable interest in the electrical properties and preparation of silicon and its alloys.

Silicon is an electronic semiconductor. Its conductivity at room temperature results principally from the presence of certain impurities. While for metals an increase in impurity content increases the resistivity, for semiconductors such as silicon the opposite occurs and, in general, the addition of impurities lowers the resistivity. Silicon materials may be classified into one of two groups depending upon the manner in which the impurities contribute to electrical properties. These have been termed for convenience p-type or n-type. P-type silicon develops a very large positive thermal emf against metals, has a Hall coefficient of positive sign and a low resistance direction in point contact rectification with the silicon positive with respect to the point. N-type silicon, on the other hand, develops a negative thermal emf against metals, has a Hall coefficient of negative sign and a low resistance direction in rectification with the silicon negative with respect to the point. Impurities which produce n-type silicon are called donors inasmuch as these elements contribute to electrical conductivity by donating electrons to an unfilled energy band in the silicon. On the other hand, elements which produce p-type silicon are known as acceptors as these impurities contribute to the electrical conductivity

by accepting electrons from a filled energy band permitting what is known as conductivity by “holes” in which the sign of the carriers appears to be positive. A general treatment of the mechanism of conduction in semiconductors from the viewpoint of modern band theory has been given recently by Pearson,² by Becker, Green and Pearson,³ and by Torrey and Whitmer.⁴

In this investigation boron and aluminum have been found to be acceptors, and phosphorus, arsenic, and antimony to be donors in silicon. Data on the effect of boron and phosphorus on the electrical properties, when present singly and in combination, have been acquired. These data are discussed in the present paper.

Raw Materials Used and Methods for Adding Second Constituents

Silicon from two sources was used in this work and these will be referred to as A and B respectively. Silicon A is a material of high purity supplied by the Electro Metallurgical Co. It is prepared by chemical purification of “commercial” silicon obtained from the arc furnace reduction of SiO_2 . It contains 99.8 pct silicon, minimum, with small amounts of calcium, iron, aluminum,

boron, and phosphorus as the principal impurities. This material was extensively employed in these studies as well as in the commercial preparation of rectifier materials. Silicon B is a material of high purity from the du Pont Co. It is prepared by a pyrolytic reduction of SiCl_4 and is free of analytically detectable amounts of boron and phosphorus. Its use permitted study of the effect of boron and phosphorus individually on the properties. This material contains, however, spectroscopic traces of a number of metals, some of which affect electrical and rectification properties.

Typical analyses for the two grades of silicon are given in Table 1.

Table 1 . . . Analyses of Silicon Used in Point Contact Rectifier Investigations

| | Silicon A† | Silicon B |
|----|------------|--------------|
| Si | 99.84 | |
| Ca | 0.003 | 0.005* |
| Na | | 0.005* |
| Cu | | 0.001* |

To make controlled additions of boron to the charge it was necessary to employ a low boron content master alloy since the quantity of boron to be added was usually only a few thousandths of one percent. The alloy containing nominally one percent boron was prepared by melting chemically pure boron with silicon A using the melting techniques for 320 g silicon

ingots to be described in the next section. This alloy was crushed in a hardened steel die, ground to a fine powder in an agate mortar, thoroughly mixed and analyzed for boron. Portions of this master alloy were then used in preparing the experimental ingots.

Direct additions of phosphorus were not feasible because of its low melting point and volatility. Instead use was made of the reaction:

When this method was used, spectrochemical analysis revealed that no calcium was retained by the silicon. Apparently also, calcium oxide formed by the reaction does not affect the properties, for the direct addition of calcium oxide to silicon ingots caused no changes in either rectifying characteristics or resistivity.

Additions of aluminum, arsenic and antimony for the qualitative tests described were made by adding these elements directly to the furnace charge.

PREPARATION OF SILICON INGOTS

The ingots of silicon were prepared in silica crucibles in an atmosphere of helium in a high frequency induction furnace. Since silicon cannot be heated by direct induction, a graphite heater which fitted around the melting crucible was used. Most of the early work was done with 45 g ingots. In preparing the ingot the charge was fused and then

slowly cooled by reducing the power applied to the induction coil. Freezing occurred largely from the top surface downward and to a lesser extent inward from the sides and upward from the bottom. During freezing, normal impurity segregation occurred. That is, the silicon at the top of the ingot was highest and that at the core of the melt was lowest in purity.

It was difficult to produce crack-free ingots by this method because of the expansion of silicon during solidification. If a mass of silicon is allowed to freeze in the normal manner, in the final stages of freezing a liquid core will be surrounded by a solid shell which may be easily ruptured by the expansion of the freezing liquid. By changes in solidification technique, however, means were found for preparing 320 g ingots free of cracks throughout the major part of the ingot. Such ingots were prepared in cylindrical silica crucibles of $1\frac{3}{4}$ in. diam and 5 in. tall. Melting was accomplished in the same manner as for the smaller charges, using graphite heaters, but freezing was controlled by gradually removing the furnace tube from the induction coil while power was still applied to the coil. Thus the top of the melt froze first, and solidification progressed slowly downward, the total time for solidification being about 20 min. This not only avoided cracking

FIG 1b—Longitudinal section of 320 gram silicon ingot.

but gave precise control over impurity distribution in the ingot. Due to segregation of impurities, the silicon at the top of the ingot had the highest purity, while the last material to freeze, at the bottom portion of the ingot, had the lowest purity. Fig 1a shows the crucible assembly, a typical 320 g silicon ingot and several sections cut from an ingot. The macrostructure of the ingot is shown in the longitudinal section, Fig 1b.

ELECTRICAL CHARACTERISTICS AND STRUCTURAL FEATURES OF THE EARLY SILICON INGOTS

The early ingots (45 g) prepared from selected lots of silicon A were found to consist of zones of p-type and n-type separated by a photovoltaic barrier.⁵ The p-type zone was located in the region of the ingot which solidified first while the n-type zone was located in the region of the ingot which solidified last. The macrostructure of the ingots is illustrated in the diagram, Fig 2. Relatively large columnar crystals extend downward from the top surface of the ingot to a depth of about one-half inch. Columnar grains are also found extending inward from the sides and upward from the bottom for about one-eighth inch. Beyond the columnar grains irregular grains are found with a network of a second phase in the grain

boundaries. The central portion of the ingot is porous presumably as a result of gas evolution in the last stages of solidification. The outer part of the columnar zone is p-type, the inner part n-type. The central portion of the ingot, containing the irregular grains is also n-type. The boundary between the p- and n-zones is approximately 1 mm in width and extends across the columnar grains, following in general the contour of the ingot surface. Since solidification occurred not only from the top surface downward but also to some extent inward from the bottom and sides of the crucible, the boundary is elliptical in cross-section and encloses the n-zone. It is evident that the boundary follows the contour of the freezing surface as it advanced during solidification. In the 320 g ingots similar effects are observed. However, in this case the solidification of the melt is substantially unidirectional, progressing from the top surface downward. The boundary then extends across the ingot and the portion of the ingot above it is p-type and below it is n-type.

If ingots are rapidly cooled by shutting off the power in the induction coil when the charge has melted, the resulting macrostructure is quite different. The crystallites are no longer columnar but are quite irregular in shape. In each grain an island of p-type is found within a matrix of n-type. The p- and n-zones are again separated by a barrier layer, but the photovoltages developed are lower than those for the barriers of the slowly cooled ingots. The structures of both the rapidly and slowly cooled ingots may be resolved microscopically and are discussed in a companion paper.⁶

Photovoltaic cells may be prepared from the slowly cooled ingots by cutting samples so that one part is p-type, the other n-type separated by the barrier. Such cells are sensitive both to visual and infra-red radiation. They are quite stable and have shown no change in characteristics over a period of several years. Moreover, the effect persists even after annealing at 1000°C for a number of hours.

Associated with the internal photovoltaic boundary are two related effects of interest. Specimens containing these boundaries show both a rectification effect and a pronounced thermoelectric effect. The rectification effect is similar to that obtained in copper oxide or selenium cells. In specimens containing these internal boundaries rectification

FIG 2—Schematic representation of 45 gram silicon ingot showing barrier.

ratios above 500 at 1 volt have been obtained. Similar rectification and photovoltaic effects in germanium have been reported by Benzer.⁷

Measurement of the resistivity of the silicon at different positions in the ingots containing p-n boundaries revealed an interesting relationship. Since increasing the concentration of impurities in semiconductors decreases the resistivity and since chemical analysis had shown the segregation of impurities in the ingots to be normal it was expected that the resistivity would decrease steadily from a high value for the material which solidified first to a lower value for the material which solidified last. Instead it was observed that in the p-region the resistivity was least for the first frozen material and that it increased with depth to a high value at the barrier. In the n-region the resistivity was highest near the barrier and then decreased with distance from the barrier reaching its lowest value in the region of the ingot which solidified last. The variation in resistivity in the p- and n-zones of a 320 g ingot is shown in Curve 1, Fig 3, which will be discussed at a later point in the paper.

Several other significant facts were observed in the early studies. For a given lot of silicon A the location of the barrier and the relative amounts of p- and n-silicon were precisely reproduced from ingot to ingot but differences were obtained between lots. The mean resistivity in the p-silicon was also related to the location of the barrier and in general it decreased as the amount of p-silicon in the ingot

increased. This clearly indicated the important role of impurities in determining properties and led to a detailed study of the electrical properties of silicon containing different alloying constituents in trace amounts.

EFFECT OF BORON ON THE RESISTIVITY AND RECTIFICATION CHARACTERISTICS OF SILICON

To obtain quantitative data on the effect of boron on resistivity and the rectification properties ingots were made with boron additions ranging from 0 to 0.01 pct. These ingots were prepared using 320 g charges of silicon A mixed with appropriate quantities of the silicon-boron master alloy. The resistivity measurements were made on rectangular specimens, approximately $1 \times \frac{1}{8} \times \frac{1}{8}$ in. in size. These were cut from the ingots so that the long axis was parallel to the top surface of the ingot. Current leads were affixed to the ends of the specimen by electroplating with nickel and soldering. The potential drop across probes on the surface of the specimen was then determined for small known currents by a potentiometric method. From these data, the dimensions of the sample and the distance between probes, the resistivity may be calculated. The sign of rectification, that is, whether the silicon was p- or n-type, was determined by applying a point contact to the surface of the specimen and observing the polarity for the easy direction of current flow.

The resistivities of the central sections of the specimens were determined for a number of vertical positions in

FIG 3—Effect of boron additions on the electrical properties of silicon A.

each ingot. Resistivity measurements in the n-region were possible, however, only for the initial sample in the series to which no boron was added. In the other ingots the n-region was too restricted in size to permit several points to be obtained.

These data are plotted in Fig 3. It will be seen that within this composition range increasing the concentration of boron in silicon A has three significant effects: 1. It increases the amount of p-silicon and lowers the position of the barrier (Curves 1, 2 and 3); if sufficient boron is added only p-type is formed (Curve 4). 2. It lowers the mean resistivity of the silicon. 3. It increases the uniformity of resistivity for a considerable part of the material in the ingot and for the 0.01 pct boron addition substantially no variation is observed throughout the ingot (Curve 4).

In the preparation of silicon point contact rectifiers the uniformity of the finished rectifiers is determined to a considerable extent by the uniformity of resistivity of the silicon used. It was desirable for this reason to attain the uniformity of the 0.01 pct boron composition at higher levels of resistivity also. To determine whether this could be achieved in silicon of higher purity, several ingots were prepared from silicon B. After fusion without alloying additions this material is p-type and its specific resistance is of the order of one ohm-cm. Addition of 0.001 pct boron, however, markedly lowers its resistivity as shown in Curve 1, Fig 4. The resistivities for this alloy ranged from 0.07 ohm-cm at the top of the ingot to about 0.03 ohm-cm at the bottom. Thus no improvement in uniformity of resistivity was obtained by

the use of silicon of extreme purity as the base material. It will be noted, however, that the resistivity *decreased* with depth in the ingot. Hence, in silicon containing only boron as the principal alloying constituent the variation of resistivity in the ingot is in the manner to be expected from a normal segregation. This is in contrast to the increase in resistivity with depth observed in ingots of silicon A containing comparable amounts of boron.

EFFECT OF BORON AND PHOSPHORUS ON THE PROPERTIES OF ULTRA-HIGH PURITY SILICON

To explain the anomalous resistivity gradient observed in ingots of silicon A the presence of a second active impurity which also affected conductivity was assumed. Further investigations revealed that traces of phosphorus were responsible for the anomalous resistivity variations and the formation of n-silicon and the photovoltaic

boundary in the ingots of this material.

To study the effects in silicon of phosphorus and boron in combination, a number of alloys were prepared from silicon B. Specimens were cut from these ingots through the central vertical axis and the resistivity and direction of rectification then determined at $\frac{1}{8}$ in. intervals. The data for typical alloys are given in Table 2 and Fig 5.

Table 2 . . . Resistivity of Silicon-boron and Silicon-Phosphorus Alloys

| Composition | Resistivity at Room Temperature of Samples from Different Locations in the Ingot | | | |
|-------------|--|------------|---------------|---------------|
| | Pct | Top ohm-cm | Middle ohm-cm | Bottom ohm-cm |
| Silicon B | +0.001 B | 0.067 | 0.050 | 0.040 |
| Silicon B | +0.01 B | 0.015 | 0.011 | 0.006 |
| Silicon B | +0.0029 P* | 0.041 | 0.034 | 0.017 |
| Silicon B | +0.0058 P* | 0.031 | 0.023 | 0.008 |

* Added as $\text{Ca}_2(\text{PO}_4)_2$.

These data show that:

1. The addition of boron to pure silicon produces p-silicon while the addition of phosphorus produces n-silicon. The resistivity of such alloys decreases with increasing concentration of the added element (Table 2 and Curves 1 and 2).

2. If ingots of silicon containing either boron or phosphorus are prepared by freezing from the top surface downward, normal segregation occurs and as a result the resistivity decreases with depth in the ingot. The rate of segregation of phosphorus is somewhat greater than that of boron as shown by a more steeply sloping resistivity curve (Curves 1 and 2).

3. If in silicon containing both boron

FIG 4—Resistivities of various alloys of silicon A and B.

and phosphorus, the boron exceeds the phosphorus by a small molar amount, of the order of 0.0002 pct, and the ingot is prepared by solidifying slowly from the top downward, then zones of p- and n-silicon will be formed, separated by the photovoltaic boundary (Curve 3). It is therefore possible to reproduce completely the resistivity, rectification and other properties observed for silicon A by adding the correct relative amounts of boron and phosphorus to silicon B. Since boron and phosphorus are both present in silicon A it is a reasonable conclusion therefore that they are the principal impurities responsible for the electrical effects observed in this material.

The mechanism of formation of the p- and n-zones and the barrier may now be interpreted in terms of an electrical interaction or compensating effect of equivalent amounts of donor and acceptor impurities. Referring to Fig 6, Curves 1 and 2 are hypothetical segregation curves for boron and phosphorus with phosphorus segregating more rapidly than the boron. At a depth of 3 in. in the ingot the curves cross and at this point the molar concentrations of boron and phosphorus are equal. Since it is believed that these impurities neutralize one another electrically, no residual impurities are available at this point to contribute to the conductivity of the silicon.* As a result high resistivity and poor point contact rectification are to be expected. This is actually the case in the region of the barrier. Above this region boron is in excess by an amount which is indicated by the difference between the two segregation curves at each location in the ingot. This amount is given by Curve 3, Fig 6 which shows that the free (excess) boron decreases with depth in the ingot from a value of 0.001 pct at the top to 0 pct at the barrier. Since boron is in excess the silicon is p-type, and since the concentration of free boron diminishes with depth, the resistivity increases correspondingly. Below the barrier phosphorus is in excess of boron by an amount equal to the difference between their concentrations at each location. The concentration of free phosphorus below the barrier, given by Curve 4, Fig 6, increases from 0 at the barrier to 0.0015 pct at the bottom of the ingot. Since phosphorus is in excess in this region the silicon is n-type and its resistivity decreases with

FIG 5—Effect of boron and phosphorus on the electrical properties of silicon B.

FIG 6—Mechanism of formation of barrier in silicon ingots.

depth in the ingot.

If silicon having the characteristics of Fig 6 were remelted and 0.001 pct more boron were added, the boron segregation Curve No. 1, would shift to the right and would intersect the phosphorus curve at a lower point. Thus, the photovoltaic barrier would appear at a lower point, the amount of p-silicon would be increased, and, since the excess of boron at the top of the ingot would also increase, the mean resistivity of the p-silicon would be lower. If instead, the boron concentration were held constant and the concentration of phosphorus reduced, Curve 2 would shift to the left, and again, the barrier would have occurred lower in the melt, the free boron concentration above the barrier would have increased and the mean resistivity would have been lowered.

It may be seen, therefore, that the electrical characteristics of the silicon ingots may be explained in terms of the differential segregation of boron and phosphorus. The hypothesis has not been checked by direct analysis, however, because of difficulties in determining accurately the small concentrations of boron, and phosphorus at the different locations in the ingot. It

is believed, however, that the hypothetical values given in Fig 6 are correct as to order of magnitude.

While these studies have been concerned principally with boron and phosphorus in silicon it has also been shown that aluminum additions produce p-type silicon, while arsenic and antimony produce n-type silicon. Moreover, photovoltaic barriers have been produced by the addition of arsenic to silicon B. It seems to be generally true therefore that the addition to silicon of elements of group 3, with 3 valence electrons produces p-silicon while elements of group 5, with 5 valence electrons, produces n-silicon.

DEPENDENCE OF UNIFORMITY OF RESISTIVITY ON THE BORON PHOSPHORUS RATIO

It has been shown that in silicon ingots containing only one principal impurity, the resistivity varies with location in the ingot. On the other hand, if 0.01 pct boron is added to silicon A practically no variation in resistivity is observed throughout the ingot. This suggested that uniformity of resistivity throughout the ingot might be related to the relative

* Similar phenomena have been reported in lead sulphide photoconductive cells by Starkiewicz, Sosnowski, and Simpson⁸ and by Sosnowski, Soole, and Starkiewicz.⁹

FIG 7—Boron additions to various mixtures of silicon A and B to obtain uniform resistivity in silicon ingots.

The values in parenthesis are the resistivity ranges observed for each composition.

amounts of boron and phosphorus in the charge and that under the correct conditions the uniformity of the 0.01 boron composition might also be attained in materials of high resistivity. To check this experimentally several melts were prepared using as raw materials different proportions of the silicon A and B, adding 0.001 pct boron to each charge. Since the A silicon contained both boron and phosphorus while the B silicon is free of analytically detectable quantities of these elements this series provided samples with a range of boron and phosphorus concentrations in which the relative proportions were systematically varied in the direction of increasing the boron to phosphorus ratio.

Resistivity as a function of location in the ingot for this series is plotted in Fig 4. As the concentration of phosphorus is decreased by increasing the proportion of silicon B in the charge, the variation in resistivity with depth decreases. The least variation is obtained with the 90-10 composition.

Thus, uniform ingots of silicon of desired resistivity may be prepared by making the proper boron additions and maintaining a critical boron to phosphorus ratio. This ratio is about 5

boron atoms for each phosphorus atom. Fig 7 shows the amounts of boron which must be added to various mixtures of silicon A and B to maintain the required 5 to 1 ratio and gives the resistivity range obtained in each ingot. It will be seen that sensibly uniform ingots with any resistivity desired in the range from 0.01 to 0.1 ohm-cm may be obtained in this way. These proportions would vary slightly if the composition of silicon A changed significantly from lot to lot.

Summary

Boron and aluminum are acceptors in silicon, and phosphorus, antimony, and arsenic are donors forming respectively p-type or n-type silicon. The presence of boron or phosphorus alone markedly reduces the specific resistance of silicon. If ingots of silicon containing small amounts of either boron or phosphorus are solidified from the top downward, normal segregation occurs and the resistivity decreases with depth in the ingot. If boron and phosphorus are present together in certain amounts, ingots may be prepared in which the top section is p-type and the bottom

is n-type silicon, in which a barrier region with interesting rectification and photovoltaic properties separates the p-type and n-type regions. In the p-zone the resistivity increases rapidly as the barrier is approached, reaches a maximum at the barrier and then decreases in the n-zone. The formation of the barrier and the variation of resistivity with depth in the ingot are interpreted as being due to interaction between donors and acceptors, in this case boron and phosphorus, in which one mol of boron compensates one mol of phosphorus. Boron and phosphorus segregate at different rates under the solidification conditions used so that in the region of the ingot which solidifies first boron is in molar excess and the silicon is p-type. In the region which solidifies last phosphorus is in molar excess and the silicon is n-type. At the location in the ingot where the molar concentrations of boron and phosphorus are equivalent, the barrier is found.

Addition of phosphorus to boron silicon compositions improves the uniformity of the resistivity in the ingot. In spite of the extreme sensitivity of the resistivity to impurities means were found to obtain sensibly uniform resistivities by maintaining the correct boron to phosphorus ratio.

Microstructures of Silicon Ingots

W. G. PFANN,* Junior Member, and J. H. SCAFF,* Member AIME

Introduction

The effects of impurities on the electrical properties of silicon are discussed in a companion paper by Messrs. Scaff, Theuerer, and Schumacher.¹ It was shown that an ingot of silicon which contained boron and phosphorus in certain concentrations consisted partly of p-silicon and partly of n-silicon² and that the common boundary between these regions was the source of a photovoltage. These features were ascribed to the segregation of boron and phosphorus during solidification of the ingot. Because of different rates of segregation the first portion of the ingot to freeze contained a molar excess of boron over phosphorus and hence was p-silicon. The last-solidified region contained a molar excess of phosphorus and was n-silicon.

This paper is concerned with the microscopic examination of such ingots. The microstructures are rather unusual in certain respects and their study has helped to show how the segregation of minor elements modifies the electrical properties of silicon. The microstructures of ingots prepared from two lots of silicon, designated 1 and 2, will be described. These lots were obtained from the Electro Metallurgical Co. Both contain 99.8+ pct silicon, but they differ in impurity analysis. For each lot will be shown the microstructure of a slowly cooled ingot, for which the time of solidification is 6 min., and that of a rapidly cooled ingot, for which the time of solidification is 2 min. The ingots were prepared from 45 g charges of silicon.

When an alloy freezes a cored structure is generally produced because of insufficient diffusion to remove concentration differences established during freezing. As a result of coring the first portion of a crystal to freeze is usually poorer in solute than equilibrium requires, while the last material to solidify is richer. In a columnar grain, growth is principally unidirectional and coring can produce a concentration gradient along the entire grain. By carrying the picture of the coring

FIG 1—Sketch showing features of slowly-cooled ingot of silicon. Vertical section through center of ingot.

process from a single grain to an entire ingot in which columnar grains are aligned more or less radially, one can easily see that a composition gradient could be established between the outside and center of the ingot. This, to a considerable extent, occurs during the solidification of a slowly cooled ingot of silicon.

Slowly Cooled Ingot

In slowly cooled ingots of both lots of silicon, columnar grains which are approximately radial in direction and longest at the top of the ingot enclose a region in which the shapes and align-

ment of the grains are considerably less regular. The central region is last to solidify and contains cavities and inclusions. The sketch of Fig 1 illustrates some of these features, as well as others which will be described below.

If a polished section of an ingot is etched in a mixture of 20 pct HF and 98 parts of HNO₃ the p-n barrier becomes visible. The overall shape of the barrier in a slowly-cooled ingot is roughly oval, as may be seen in Fig 1. The proportion of n-silicon, that is, the region enclosed by the barrier, is considerably greater in ingots of lot 1 than in those of lot 2.

A sample about $\frac{1}{2} \times \frac{1}{8} \times \frac{1}{8}$ in. was cut from a slowly cooled ingot of lot 1 with its long direction extending from the top of the ingot to the porous region. Thus its upper half was p-silicon, its lower half n-silicon. A longitudinal face was polished and etched in the acid mixture. The areas of interest are identified in Fig 2. A band of parallel markings extends across the sample in the columnar region. These striae are roughly parallel to the upper surface of the ingot and cross grain boundaries with only slight deviations. They are quite distinct in the n-silicon,

especially near the p-type area. Striae are present in the p-silicon but are not visible in Fig 2.

Photovoltaic activity is confined to points on the sample which are common to both p- and n-silicon. It was possible to determine the locations of such points very accurately by connecting a suitable recording instrument to the ends of the sample and then exploring the specimen surface at high magnification, using the illuminating beam of the microscope as a source of light.

A portion of the p-n region of Fig 2 is shown at higher magnification in Fig 3.

Examination of Fig 2, 3 and 5 will show that although a few n-striae are completely isolated, most of the n- and p-striae are connected to the main bodies of n- and p-silicon respectively. The striae may be said to be interlocking rather than alternating. Hence the boundary which is common to the main bodies of n- and p-silicon is quite long. A result of this feature is an enhancement of the photo-current obtained on illumination.

The difference in the behavior of the two etchants which have been used in this study is interesting. A warm, aqueous, 5 pct solution of sodium hydroxide forms etch-pits whose shapes depend on crystal orientation. At moderate and low magnifications this effect is seen as a uniform darkening of entire grains which varies in degree in individual grains. Hence this reagent is helpful in showing grain size and shape. It is entirely insensitive, however, to the presence of the p-n boundary or the effect which produces the striae.

On the other hand the mixed acid etchant reveals the striae and the p-n boundary. It produces an overall brightening and delineates the grain boundaries.

The following explanation is advanced for the microstructures of a slowly cooled ingot:

When freezing begins columnar grains form at the outside of the melt and grow inward, those originating at the upper surface growing most rapidly. At any time during solidification the shape of the liquid-solid interface roughly parallels the outer surface of the ingot. This advancing front is more or less unbroken except for small differences in growth of individual grains and irregularities at the grain bound-

aries. The striae in the columnar region are believed to be the result of minor undulations in the composition gradient which are caused by disturbances in the liquid adjacent to the advancing solid. They record the positions of the liquid-solid interface throughout the solidification of the columnar region. Since an overall concentration gradient of impurities is established during the freezing of the columnar grains the striae may also be regarded as contours of constant composition.

An explanation of the alternating strips of p-silicon and n-silicon at the boundary is given by the hypothetical curve of Fig 4, which shows the concentrations of excess boron or phosphorus as a function of distance from the top of the ingot for a single columnar grain. The reversals represent the local variations in composition which are associated with the striae, while the major trend of the curve depicts the general effect of coring on the difference between the concentrations of phosphorus and boron. Since silicon changes from p-type to n-type at zero difference, it is possible to have a number of alternate bands of p-silicon and n-silicon in a polished section if the fluctuations are of sufficient amplitude. This situation is shown in Fig 4, where two narrow strips of p-silicon and two of n-silicon appear, and is a characteristic feature of slowly cooled ingots, as may be seen from Fig 5 and from Fig 2 and 3. The dark edges between the p- and n-areas in Fig 5 do not necessarily indicate the presence of a substance at the boundary but are an

FIG 3—Area from Fig 2. $\times 50$.

FIG 4—Relation between excess impurity concentration and distance from top of ingot.

etching effect. The p-silicon is attacked more rapidly by the acid etchant, leaving raised peninsulae of n-silicon whose sides are oblique, and hence are dark in vertical illumination.

Rapidly Cooled Ingot

If the molten silicon is cooled rapidly, nucleation occurs throughout the melt rather than only at the surface and instead of columnar crystals an equiaxed grain structure results. Such an ingot differs from a slowly cooled ingot electrically and microstructurally. During solidification coring produces at the center of each grain a region which is poor in impurities and which is surrounded by layers of increasingly higher concentration. In contrast, the region weak in impurities in a slowly cooled ingot is at the outside of the ingot and is continuous. In a rapidly cooled ingot inclusions are found in the last-solidified

parts of each grain and are distributed throughout the ingot instead of being concentrated in the center, as in a slowly cooled ingot. In short, in a slowly cooled ingot segregation may be regarded as a feature of the ingot as a whole, while in a rapidly cooled ingot it is in general localized to individual grains.

If the relative concentrations of boron and phosphorus vary in a single grain as they do in a slowly cooled ingot, one would expect to find a p-n boundary having the shape of a closed figure in that grain. Examination of rapidly cooled ingots has shown this to be so. The microstructures may be described as islands of p-silicon in a background of n-silicon. Measurements of the direction of point contact rectification, made by using a sharply pointed probe to touch individual grains, showed that invariably the islands were p-silicon while the surrounding areas were n-type.

Fig 6 shows an area in a rapidly cooled ingot of lot 1 in which several islands of p-silicon are visible. These islands were concentrated at the top of the ingot where, despite the non-columnar grain growth, freezing did take place first. The remainder of the ingot was entirely n-type. Thus, in addition to local coring in each grain, some segregation had occurred in the ingot as a whole.

An area from a rapidly cooled ingot of lot 2 is shown in Fig 7 and 8. Here the p-n boundaries are near the grain boundaries. The major part of each grain is p-silicon surrounded by a thin

strip of n-silicon. Again some segregation occurred over the ingot as a whole, as some grains at the top of the ingot contained only p-silicon and the grains containing the greatest proportion of n-silicon were at the center of the ingot.

It was stated in the discussion of slowly cooled ingots that those of lot 2 contained more p-silicon than those of lot 1. As Fig 6 and 7 show, this relationship is also true for the individual grains in rapidly cooled ingots.

Although the p-n boundaries in the two types of ingot are unlike in many respects, they are basically similar. Their shapes and locations differ because the ingots solidify in dissimilar ways. The appearance of the boundary in a slowly cooled ingot is further modified by the effect responsible for the striae. Apparently this effect is seldom present in rapidly cooled ingots.

The irregular shapes of the p-n boundaries, especially in rapidly cooled ingots, make it unlikely that they are localized to certain crystallographic planes. Their locations and appearance at high magnification distinguish them from grain boundaries. Illustration of these points is offered in Fig 9 and 10.

Summary

The microstructures of ingots of two lots of silicon have been described, both as prepared by slow cooling and by rapid cooling. The dependence of the distribution of the p- and n-regions on segregation has been indicated. When the ingot freezes slowly the grains are columnar, the regions of p-silicon form

a continuous zone which encompasses the n-silicon, and the p-n boundaries are relatively continuous. When cooling is more rapid, nucleation occurs throughout the melt and grain growth is disorderly, with the result that the p-silicon and the p-n boundary in each grain are separated from the corresponding regions in adjacent grains by layers of n-silicon.

Controlled Drying of Retorts

R. R. FURLONG* and D. H. WERTZ*

Dry room equipment at Donora Zinc Works is of the design which prevailed at the time the plant was built in 1915. It consists of 11 adjoining rooms, each being 99 ft long, 11 ft wide, and 7 ft high and having a capacity for 1040 retorts. Heat is supplied by steam coils beneath the slatted wood floor and by warm air ducts at the ceiling. Drying practice is about the same as that generally followed in the industry except that, under normal zinc furnace operations, the maximum drying time is 45 days.

During certain seasons of the year the drying process was seriously affected by varying weather conditions which frequently resulted in a scrap loss of 5 to 7 pct. Because of these unfavorable conditions, which caused uneven drying and strains in the retorts, increased retort failures in the zinc furnaces were recorded. Regulation of temperature and humidity under all conditions appeared to be the logical solution of this problem.

Controlled drying had been developed for a number of ceramic products and investigation of several such drying processes in this area revealed favorable results. Along with control of drying conditions and the attendant decrease in scrap losses, plant operators also reported a material reduction in drying time.

Another factor affecting the decision to proceed with this development was

the drastic change in market conditions for retort clay. Curtailment of shipments from the chief source of supply made it necessary to proceed with blending of other available clays, but quality of these clays was questionable for adequate retort life in the 24 hr furnace cycle. Rapid furnace testing of new mixtures was desirable but impossible with the prolonged drying schedule. Therefore development of a controlled drying process for zinc re-

torts offered the solution to the problem of rapid testing of retort mixtures.

Description of Process and Equipment

The freshly extruded retort is cylindrical in shape, 58 in. long, 9 in. id and has $1\frac{1}{8}$ in. side walls. One end is closed and approximately 2 in. thick. The moisture content of this "green" retort is about 17 pct which means a necessary removal of 30 lb of water per retort. Retorts are set on the slatted floor of the dry room with the closed end down.

The controlled drying process depends upon the circulation of a large volume of conditioned air at low velocity. To provide for uniform distribu-

FIG 1—Front view of Carrier Heater unit.

San Francisco Meeting, February 1949.

FIG 2—Rear view of Carrier Heater unit.

FIG 3—View of retorts in drying room.

tion of the air stream, the heater units should discharge into a large chamber. The only available space for this, in the existing dry rooms, was under the slatted floor. Two inverted type Carrier Heater units, each with a fan capacity of 17000 cfm, were installed in the middle one of three dry rooms, and connected to each adjacent room with short ducts leading into wall openings above and below floor level. Manually operated interlocked dampers within the unit regulate the flow of air to either room.

To control conditioning of the air stream, each heater unit is provided with wet and dry bulb temperature instruments located beneath the floor of each room opposite the duct opening. These control instruments actuate air operated valves on the steam lines to the heater coils and to the steam spray (Fig 1). These supply heat and moisture as required. During the drying cycle a slight pressure is maintained in the dry room and make-up air is introduced through a fresh air damper (Fig 2). This damper, located in the rear wall of the heater unit above the steam coils, is operated by an air valve which in turn is controlled by the dry bulb instrument.

After considerable experimental work a standard practice for quick controlled drying of zinc retorts has been developed to suit conditions at this plant.

Loading of the room requires about two days production from the retort press. Retorts are placed in staggered

rows 3 in. apart and this widespacing provides free movement of the rising warm air around the retorts (Fig 3). Incidentally, this spacing has reduced the capacity of each room from 1040 to 760 retorts.

After loading, the stack damper and doors of the room are closed and retorts are allowed to stand at existing conditions until the following morning. Air circulation is then started and continued for 48 hr at a dry bulb temperature of 120°F and 72 pct relative humidity. The wet bulb temperature for this humidity is 110°F which temperature remains constant throughout the drying cycle. On the third day the dry bulb temperature is held at 130°F for 8 hr with a relative humidity of 53 pct. For the next 16 hr the dry bulb temperature is fixed at 140°F with a corresponding decline in relative humidity to 38 pct. During the first 6 hr of the fourth day the dry bulb temperature is increased in 10° intervals until 170°F is reached, with a final relative humidity of 17 pct. At this point the fresh air and stack dampers are opened. Fresh air heated to 170°F is allowed to sweep through the room for the next 16 hr to complete the drying cycle. Steam is then shut off and the fan is used to cool the room.

Summary

1. It is evident from the above description of drying practice that the

principles of controlled drying can be beneficially applied to the manufacture and quick testing of zinc retorts.

2. The drying cycle has been reduced from 45 days to 4 days with assurance that drying conditions can be duplicated. This feature is extremely valuable in the rapid testing of new retort mixtures.

3. Retort losses in drying have been reduced to less than one percent. This is about half the normal loss expected with the slow drying practice.

4. Close regulation of temperature and humidity has eliminated their fluctuation caused by variations in the weather.

5. Numerous zinc furnace tests have not shown any failure of retorts which could be associated with the quick drying process. At the same time no improvement in service in the furnaces has been detected.

6. The capacity of the present installation is not large enough to supply total retort requirements for current furnace operations. Therefore the equipment is used to quick-test the quality of retort mixtures to be dried by the slow process, and as additional capacity for emergency production. In these respects the installation has been satisfactory.

7. Quick drying equipment of sufficient capacity for the entire smelting furnace requirements would reduce the number of drying rooms by one-half with a corresponding decrease in retort inventory.

The Study of Grain Boundaries with the Electron Microscope*

J. F. RADAVIDH†

Introduction

Many heats of steel of low carbon value have been known to produce brittle pieces of steel. The brittleness is believed to be due to the impurities located within the grain boundaries. Such brittle steels have been examined with an optical microscope to ascertain the nature and the amount of the impurities present at the grain boundaries. Due to the relatively low resolving power of the optical microscope, the impurities are not visible in fine detail.

The writer obtained some sheet steel and proceeded to determine the location of the impurities and to show the application of the electron microscope to the study of grain boundaries. One sample was known to be capable of becoming embrittled, whereas another sample was believed to be much less susceptible to embrittlement.

Treatment of Specimens

The specimens were embrittled by annealing above the A_3 point under mildly oxidizing conditions. One piece of ingot iron could not withstand a 90° bend, whereas another piece of ingot iron was not affected and could withstand a 90° bend. The brittle piece was then annealed at a high temperature in a hydrogen atmosphere.

The annealed ingot iron was termed *cured* and could withstand a 90° bend very easily. The three specimens examined will be designated as *brittle*, *good*, and *cured* in the discussion that follows.

Procedure

The sizes of the specimens were as follows: one piece of brittle ingot iron— $\frac{3}{8}$ by $\frac{1}{8}$ in.; one piece of good ingot iron— $\frac{3}{8}$ by $\frac{1}{8}$ in.; one piece of cured ingot iron— $\frac{3}{8}$ by $\frac{1}{8}$ in.

The specimens were too small to be

FIG 1—Cut-down screen for narrow specimens.

polished by hand and therefore were mounted in bakelite. The polishing procedure was carried out in the conventional manner with the use of 1/0 through 3/0 papers, and the final polish was done with alumina on a billiard cloth. The specimens were then etched in a 4 pct solution of picral in alcohol, and then they were examined through an optical microscope. An area was chosen that showed distinct grain boundaries, and an effort was made to keep near this area when pulling the replicas

REPLICA TECHNIQUE

The replica technique used in the preparation of the replicas for examination under the electron microscope is described in *Electron Metallography*.¹ It consists essentially of the following steps:

1. Obtaining a suitably etched specimen.
2. Applying a swab of ethylene dichloride on the surface.
3. Applying a formvar solution on the surface.
4. Placing a screen on any desired spot.
5. Breathing on the formvar layer.
6. Applying scotch tape on the screen and film.

7. Pulling the film and the screen up with the Scotch tape.

8. Separating the screen from the Scotch tape.

This replica technique is very similar to the one described by Harker and Shaefer.² However, with the added step, the percentage of replicas removed is very much higher regardless of the length of the time from the etching of the specimen to the actual pulling of the replica.

The replicas were then shadow cast with manganese at a filament height to replica distance ratio of $1\frac{1}{2}:7$. This produced a very high contrast replica for use in the electron microscope.

One of the difficulties encountered with this study was the restricted area of the specimen. The width of the specimens was the same as that of the 200 mesh nickel supporting screen. In order to increase the effective area, the screens were cut down as shown in Fig 1. The arrow indicates the direction in which the replica was pulled. This operation made it possible to obtain a large percentage of good replicas.

Fig 3 shows an electron micrograph of a brittle piece of ingot iron and a grain boundary that was polished mechanically. The surface is very rough probably due to the incomplete removal of the flowed layer by the picral etchant. The grain boundary does show evidence of impurities. It was decided to electropolish the specimens to obtain a much smoother surface than the one obtained by mechanical polishing.

ELECTROPOLISHING

The specimens were cut in half to expose the metal on the back side. The exposed metal had sufficient area to make good electrical contact and electropolishing was carried out easily.

The conditions for electropolishing were 0.9 amp, 35 volts, and 25 sec. in an electrolyte composed of 850 cc of ethyl alcohol, 100 cc distilled water, and 50 cc of perchloric acid.

The polished specimens were then etched in the 4 pct picral solution for a shorter time than was necessary for

specimens polished mechanically. The grain boundaries were clearly defined and the number of scratches was small, Fig 2.

EXAMINATION OF THE GRAIN BOUNDARIES

In order to gain the maximum contrast, the objective aperture was installed in the electron microscope. The background electrons were eliminated, and the electron micrographs showed good contrast. The rough surface background caused by the flowed layer as seen in Fig 3 was eliminated.

The brittle piece of ingot iron was carefully examined to locate the grain boundaries and whatever impurities the grain boundaries might contain. It was noticed that a large quantity of impurities existed at the grain boundaries. These findings were recorded on photographic plates and are represented by Fig 4-8.

The good piece of ingot iron was then similarly examined to observe the amount of impurities present. Fig 9-12

show the typical structures that were observed in the electron microscope.

The cured piece of ingot iron was then similarly examined to see the effects at the grain boundaries produced by the hydrogen anneal. Fig 13 and 14 show two representative pictures of the cured metal.

Discussion of Micrographs

The optical micrograph is included to show the grain boundaries at 1000 \times . The electron micrographs will be divided into three groups showing the grain boundary structure of each group. The electron micrographs were taken at 7500 \times and then enlarged to 18,500 \times .

The electron micrographs illustrated are lacking in detail especially at the grain boundaries. This loss of detail is due to the enlargements and printing from the original plates.

BRITTLE IRON

Fig 3 is an electron micrograph show-

ing the lack of contrast due to the rays of scattered electrons which build up a general hazy background. The impurities are shown at the grain boundaries. The white areas are shadows cast by the oblique rays of evaporated manganese. The stringers shown in the ferrite areas are probably due to the incomplete removal of the flowed layer by the etching solution.

Fig 4 was taken with the objective aperture in the electron microscope. The grain boundary is very regular and is about 0.5 microns wide.

Fig 5 shows the intersection of the three grains of ferrite. In each case the boundary is large and the impurities are clearly shown. The width of the grain boundaries is about 0.4 to 0.6 microns. The same size boundary exists in Fig 7, but the shadow cast was parallel to the grain boundary. This produced a loss of details within the shadows.

Fig 7 shows the structure of the ferrite (top) which is rough and projecting. The lower grain which is

FIG 12—Ingot iron good. Mag. 18,500 \times .

FIG 13—Ingot iron cured. Mag. 18,500 \times .
Reduced approximately one-fourth in reproduction.

oriented differently is smooth, with particles of manganese producing shadows. The grain boundaries of Fig 7 and 8 show the impurities, and the average width of the grain boundaries is about 0.5 microns.

GOOD IRON

Fig 9, 10, and 11 show the grain boundaries as narrow areas in comparison to the brittle ingot iron. The width of the grain boundaries is about 0.08 microns. However, in Fig 12 the grain boundary is wide and contains some impurities. Due to the printing process, the details within the grain boundary are missing.

FIG 14—Ingot iron cured. Mag. 18,500 \times .
Reduced approximately one-fourth in reproduction.

CURED IRON

Fig 13 and 14 show the condition of the grain boundaries after the hydrogen anneal. The most noticeable fact is that the impurities have been completely removed. The grain boundaries show the grains meeting each other very tightly. The white grain boundary effect seen in Fig 13 and 14 is due also to the printing process which prohibits the fine details from being reproduced.

Fig 5 and 13 show the striking comparison of the grain boundary conditions of the brittle and the annealed ingot iron specimens.

Conclusions

From the electron microscope examination of the various pieces of ingot iron which were brittle, good, and cured, it is evident that the cause of the embrittlement may be due to the segregation of impurities at the grain boundaries. This embrittling material

is probably in the form of various oxides.

In the brittle state, the grain boundaries have been broadened by the impurities which have segregated at the grain boundaries. From observation of all the plates, it has been concluded that the metal as a whole becomes brittle if the width of the grain boundaries is 0.4 microns or greater. The grain boundaries of the brittle ingot iron fall in such a range.

The good piece of ingot iron has an appreciable amount of impurities at its boundaries, but the distribution is such that the grain boundaries are not excessively large. The grain boundaries average from about 0.08 microns to 0.2 microns. It is believed that with an additional oxidizing period the good ingot iron would have gathered more impurities at the boundaries and become brittle.

The hydrogen anneal has caused the grain boundaries to give up the im-

purities and the bond between grains reestablished itself. There were no evidences of impurities within the grain boundaries of the cured iron. The ferrite grains were a great deal smoother and contained less inclusions than were found in the brittle and good ingot iron.

The electron microscope has proven that an actual study of the grain boundary size in various metals can shed light on many problems against which metallurgists have come. In the study of this problem, the electron microscope has shown that the grain boundaries may hold the answers to many properties of polycrystalline metal.

Transformation of Gamma to Alpha Manganese

E. V. POTTER,* H. C. LUKENS,* and R. W. HUBER,† Junior Member AIME

For a number of years, it has been known that manganese made by electro-deposition under certain conditions is ductile while under other conditions it is very brittle. The ductile metal is gamma manganese normally stable only between 1100 and 1138°C¹; the brittle metal is alpha manganese, stable up to 727°C. The ductile metal is not stable, but gradually changes to the brittle form; the time required to complete the transformation is about 20 days at room temperature. Other observations have indicated that the transformation is completed in 10 to 15 min. at about 125°C, while at -10°C, no appreciable change occurs in 9 months.

The properties of gamma and alpha manganese in the pure state are ordinarily difficult to determine because the gamma structure cannot be retained by normal quenching procedures and alpha manganese is so brittle, it is difficult to obtain specimens free from flaws. In a recent investigation² some properties of gamma and alpha manganese were determined by studying the ductile electrolytic metal and determining the changes in its properties as it transformed to the brittle alpha form. These investigations provided an excellent opportunity for following the progress of the transition and studying its mechanism. The results of a series of such investigations are reported in this paper.

Procedure

Various properties of manganese were determined starting with the metal in the original ductile gamma form and following the subsequent changes in its properties as the metal transformed to the brittle alpha form. These observations were made at various temperatures, the data providing information regarding the mechanism of the transformation as well as

the effect of temperature on the transition rate. Structure and resistivity values gave the most significant results, so this paper is concerned primarily with them.

The structure was studied microscopically as well as by X ray diffraction. The resistivity was determined on strips of the metal by measuring the potential drop across a given length of the specimen. Current was passed through the specimen by wires soldered to its ends, and the potential connections were made by wires looped around the specimen near its center. The current was determined by the potential drop across a standard resistor connected in series with the specimen, the potential drop being measured on a potentiometer.

In the temperature range from room temperature to 100°C an ordinary drying oven was used to heat the specimen. This was entirely satisfactory except at 100°C, where the time required to heat the specimen was long compared to the transition time, making the initial section of the resistivity curve unsatisfactory. To overcome this limitation, at 100°C and higher a thermostatically controlled oil bath was used to heat the specimens. The block on which the specimen was mounted was plunged into the hot oil at the start of each test. The

heating time was thereby reduced from 5 min. to about 6 sec, and dependable resistivity values could be obtained through 160°C. At this point the whole transition, including the warm-up time for the specimen, required only about 20 sec and it was not considered worth while trying to extend the temperature range further.

Aside from the heating problem, the problem of making a sufficient number of accurate resistivity determinations became more and more difficult as the temperature was raised. Using the manually operated potentiometer, 100°C was about as far as it was possible to go. At this temperature and above, a self-balancing photoelectric recording potentiometer was used. Its response was quite rapid, and it proved to be entirely satisfactory all the way through 160°C, where the tests were stopped because of the specimen heating problem rather than any limitation of the potentiometer recorder.

The metal used in these tests was prepared at the Salt Lake City laboratory of the Bureau of Mines. The method of preparation is discussed in a paper by Schlain and Prater.³ The sheets were about 2 $\frac{3}{8}$ by 5 $\frac{3}{16}$ in. and varied from 10 to 16 mils in thickness. They could be cut readily into pieces suitable for the various tests. X ray and microstructure determinations were made on pieces about $\frac{1}{8}$ to $\frac{1}{4}$ in. wide and about 1 in. long, while resistivity measurements were made on strips as long as possible and about $\frac{1}{2}$ in. wide. The thickness of each sheet was not uniform over all its surface. This had no bearing on the X ray and microstructure determinations, but sections as nearly uniform and free from flaws as possible were chosen for the resistivity determinations.

The gamma manganese was electro-deposited at 30°C, the time of deposition ranging from 5 to 12 hr for each sheet. Whenever possible, the tests were started directly after the metal was stripped from the cathode; otherwise the sheet was placed immediately

in an electric refrigerator and stored at about -10°C until needed. In no case was there any appreciable difference in the behavior of the fresh and stored metal.

Results

X RAY AND MICROSTRUCTURES

Microscopic examinations of the specimens were unsatisfactory. In no case could the individual grains be identified or the different phases be distinguished. The grains are apparently too small to be studied by this method. The X ray diffraction patterns gave good results, however. In each case the pattern changed from that for gamma manganese to that for alpha manganese, the relative intensities of the two patterns changing as the transition progressed. No attempt was made to determine quantitatively the relative amounts of the two phases. It is significant, however, that no beta manganese was found at any time. Since this is the intermediate phase between alpha and gamma manganese, it might be expected that the beta phase would be an intermediate step in the transformation. Either this is not the case and gamma manganese transforms directly to alpha manganese, or any beta manganese formed transforms so rapidly to alpha manganese that the amount of beta manganese present at any time is very small.

Resistivity

Resistivity measurements were made during the progress of the transformation from gamma to alpha manganese at temperatures ranging from 20 to 160°C . The results are given in Tables 1 to 11. Examination of these data shows the change in resistivity to be slow at first, increasing as the transition progresses and again slowing as the transition nears completion. This is shown clearly in Fig 1, which shows the variation of resistivity with time at 25°C . This S-shaped curve is typical of all the resistivity data as well as the hardness and density data and is apparently characteristic of this type of transition. The effect of temperature on the transition rate is shown in Table 12, where the time required for the transition to be about half completed is given for various temperatures. The time ranges from 455 hr at 20°C to about 8 sec at 160°C , decreasing

FIG 1—Variation of resistivity with time at 25°C .

ing by a factor of about 2 for each 10°C rise in temperature.

Transformation Theory

Data such as those given in Tables 1 to 11 provide an excellent means for studying the transition of gamma manganese and determining the transition-rate constants, but before this can be done it is necessary to develop a theory for the mechanism of the transformation which will satisfactorily explain the observed behavior. Let us assume that the resistivity at any time is given by the expression

$$R = \alpha R_{\alpha} + \gamma R_{\gamma} \quad [1]$$

where R is the measured resistivity, R_{α} and R_{γ} are the resistivities of alpha and gamma manganese, respectively, and α and γ are the fractions of alpha and gamma manganese present at any time. It is assumed, based on X ray observations, that no beta manganese is present. Then, since $\alpha + \gamma = 1$, the amount of alpha and gamma present at any time is given by the relations:

$$\alpha = \frac{R - R_{\gamma}}{R_{\alpha} - R_{\gamma}} \quad [2]$$

and

$$\gamma = \frac{R_{\alpha} - R}{R_{\alpha} - R_{\gamma}} \quad [3]$$

From Eq 2 and 3 we see that

$$\frac{d\alpha}{dt} = \frac{1}{R_{\alpha} - R_{\gamma}} \frac{dR}{dt} \quad [4]$$

and

$$\frac{d\gamma}{dt} = \frac{-1}{R_{\alpha} - R_{\gamma}} \frac{dR}{dt} \quad [5]$$

or that the rate of change of the amounts of alpha and gamma manganese with respect to time is directly proportional to the rate of change of resistivity. Thus, with only a change in vertical scale, resistivity curves such as Fig 1 also represent the variation of the amount of alpha and gamma manganese with respect to time.

From Fig 1, based on the above discussion, we see that the rate of

formation of alpha manganese is slow at first, gradually increasing to a maximum near the point where half of the gamma manganese has transformed and again decreasing as the amount of untransformed gamma manganese decreases toward zero. The slow rate of formation of alpha manganese at the start, accelerating as the transition progresses, can be explained as follows: In its initial state the metal consists of atoms arranged in the form of a face-centered tetragonal structure characteristic of gamma manganese, each

unit cell consisting of 4 atoms. Alpha manganese, however, has a body-centered cubic structure consisting of 58 atoms to the unit cell. Before the transition can start, it is necessary that enough atoms arrange themselves in the form characteristic of alpha manganese, so that a particle of alpha manganese can form. This will occur as a result of the random motion of the atoms in the metal, the probability of enough atoms becoming arranged in the proper grouping being less for alpha manganese, however, than it would be for a more simple structure. Alpha manganese has a higher density than gamma manganese, so once a particle of alpha manganese has formed, it will try to occupy a smaller volume than the original gamma manganese, and owing to interatomic forces, the alpha manganese particle and the surrounding gamma manganese will be under stress. Alpha manganese is the lower energy form, but particles of alpha manganese below a critical size will be unstable and reconvert to gamma manganese. Particles large enough for the decrease in volume energy to exceed the increase in surface and strain energy will be stable however, and form nuclei about which more alpha manganese can form. The rate of formation of alpha manganese about any nucleus will depend on the size of the nucleus and will increase as the particle grows, new alpha manganese being formed at an accelerating rate around each nucleus. New particles of alpha manganese will also be forming throughout the body of the metal, and each of these will grow, the rate of formation of alpha manganese accelerating as the transformation progresses.

The acceleration in growth of an individual particle will continue only so long as the alpha manganese particle is completely surrounded by gamma manganese. Ultimately a point will be reached where two or more alpha manganese particles will touch each other. Their active surface is then decreased and the acceleration in growth is less. This will occur at more and more points in the specimen as the transition progresses, until a point is reached where the rate of formation of alpha manganese is a maximum and must then decrease, necessarily becoming zero when there is no more gamma manganese. Thus, curves of the general shape shown in Fig 1 can be explained on the basis of the variation with time of the interface between two

FIG 2—Log $(R - R_\gamma)/(R_\alpha - R)$ vs. time at 140°C.

phases, the interface necessarily being zero at the beginning and end of the transition and a maximum somewhere in between.

When the particles of alpha manganese are completely surrounded by gamma manganese, the rate of formation of the alpha manganese will be proportional to the volume of the gamma manganese under stress. This volume will be the product of the interface area times an effective depth of penetration of the stress into the surrounding gamma manganese. It is reasonable to suppose that this depth of penetration will be proportional to the size of the alpha-manganese particle. Then, the effective volume of the gamma manganese under stress will be proportional to the volume of the alpha-manganese particle, or

$\frac{d\alpha}{dt} = K_1\alpha$. This expression is incomplete, however, as it does not provide

for a decrease in $\frac{d\alpha}{dt}$ as the alpha-manganese particles grow together and the interface area decreases. This factor cannot be accounted for in an exact manner, but the desired effect can be obtained by multiplying by gamma, as in the following equation:

$$\frac{d\alpha}{dt} = K_1\alpha\gamma \quad [6]$$

FIG 3—Log $(R - R_\gamma)/(R_\alpha - R)$ vs. time at 115°C.

Thus, in the early stages of the transition, when gamma is nearly 1, Eq 6 says that $\frac{d\alpha}{dt} = K_1\alpha$ as was reasoned above. However, as alpha increases, gamma decreases, and $\frac{d\alpha}{dt}$ increases until alpha equals gamma or the transition is half complete. After this the decrease in gamma causes $\frac{d\alpha}{dt}$ to decrease, approaching zero as the transition nears completion. Introducing gamma into the equation may not be strictly correct, but it does have the

desired effects of reducing the rate of formation of alpha manganese as the particles grow and their surfaces meet and of reducing the rate to zero at the end of the transformation.

From Eq 6 by integration we get

$$\ln \frac{\alpha}{1-\alpha} = \ln \frac{\alpha}{\gamma} = K_1 t + C$$

and from Eq 2 and 3

$$\ln \frac{R - R_\gamma}{R_\alpha - R} = K_1 t + C_1 \quad [7]$$

This equation indicates that, if the above theory is correct, values of

$\ln \frac{R - R_\gamma}{R_\alpha - R}$ when plotted against t

should follow a straight line. Using values of R from Tables 1 to 11,

values of $\log \frac{R - R_\gamma}{R_\alpha - R}$ were calculated

and plotted against time. Logarithms to the base 10 were used instead of natural logarithms for convenience. Typical curves are shown in Fig 2 and 3. In every case, by proper choice of R_α and R_γ , curves such as Fig 2 can be obtained and represented by a straight line if the deviations shown are not considered serious or significant. On the other hand, curves such as shown in Fig 3 can also be obtained in which the upper portion of the curve fits a straight line very well, whereas the lower portion deviates more and more toward zero time. Considering the accuracy with which the resistivities can be determined and the closeness to which the points fit a smooth curve, curves such as Fig 2 were not considered satisfactory fits and an attempt was made to modify Eq 6 so as to obtain a fit throughout the whole transition comparable in that shown in Fig 3 for the upper part of the curve.

From Fig 3, it can be seen that the slope of the actual curve, $\log \frac{R - R_\gamma}{R_\alpha - R}$ versus time, is less during the first half of the transformation than that of the straight line determined by the upper half of the curve. The deviation of the actual values of $\log \frac{R - R_\gamma}{R_\alpha - R}$ from a projected straight line fitting the upper half of the curve is very nearly proportional to $\frac{1}{\alpha}$. Therefore, by subtracting a term $\frac{K_2}{\alpha}$ from

Table 10 . . . Variation of Resistivity with Time at 150°C

$\log \frac{R - R_\gamma}{R_\alpha - R}$, it should be possible to obtain points following a straight line throughout the whole transition. Eq 7 thus becomes

$$\ln \frac{\alpha}{\gamma} - \frac{K_2}{\alpha} = K_1 t + C$$

or

$$\ln \frac{R - R_\gamma}{R_\alpha - R} - K_2 \frac{R_\alpha - R_\gamma}{R - R_\gamma} = K_1 t + C \quad [8]$$

The data shown in Fig 2 were recalculated on this basis and are shown in Fig 4. It can be seen that, by proper choice of R_α , R_γ , and K_2 , the data fit a straight line very well from practically zero time to completion of the transition. The deviation at zero time cannot be considered serious, as it is uncertain just when the specimen has become uniformly heated, and readings before this are unreliable.

Eq 8 seems to be a satisfactory representation of the experimental data, and from it, by differentiation, we get the relation,

$$\frac{d\alpha}{dt} = K_1 \alpha \gamma \frac{\alpha}{\alpha + K_2 \gamma} \quad [9]$$

Comparing this equation with Eq 6, we see that a new factor, $\frac{\alpha}{\alpha + K_2 \gamma}$ has been introduced. When alpha is small compared to $K_2 \gamma$ this factor equals $\frac{\alpha}{K_2}$ and approaches zero as alpha ap-

proaches zero, making $\frac{d\alpha}{dt}$ smaller during this part of the transition. The factor $\frac{\alpha}{\alpha + K_2\gamma}$ increases as alpha increases, becoming $\frac{1}{2}$ when alpha equals $K_2\gamma$, and is equal to 1 when alpha is large compared to $K_2\gamma$. In the latter case Eq 9 is equivalent to Eq 6, and represents the upper part of the curve in Fig 3. This equation was obtained empirically and has no obvious physical interpretation. Its exact form cannot be considered too significant. A number of equations could be obtained which might represent the experimental data as well. One of these is

$$\frac{d\alpha}{dt} = K_1\alpha\gamma(1 - e^{-\frac{\alpha}{K_2\gamma}}) \quad [10]$$

In this case, the factor $(1 - e^{-\frac{\alpha}{K_2\gamma}})$ is equal to $\frac{\alpha}{K_2}$ as alpha approaches zero, increases to 0.632 when $\alpha = K_2\gamma$, and becomes 1 when alpha is large compared to $K_2\gamma$. This is almost exactly the way the factor $\frac{\alpha}{\alpha + K_2\gamma}$ in Eq 9 varies with alpha. Again, however, this factor has no obvious physical significance, and in addition Eq 10 cannot readily be integrated and the constants cannot readily be evaluated from the experimental data. The important thing to be noted is not the exact form of the modifying factor but rather the manner

FIG 4—Log (R - R_γ)/(R_α - R) - K₂ $\frac{R_{\alpha} - R_{\gamma}}{R - R_{\gamma}}$ vs. time at 140°C.

in which it affects the value of $\frac{d\alpha}{dt}$ as alpha varies.

The physical nature of the factors retarding the transformation in the initial stages is not known. It is probably due to the greater tendency for small alpha-manganese particles to revert to gamma manganese than for the larger ones. This would slow the net formation rate of alpha manganese at first. Formation of beta manganese might also be a factor, but it is hard to see how this could have a great effect, since more than a few percent of beta manganese could hardly be present without being detected and such small amounts could hardly affect the transition appreciably.

The transformation theory presented above is necessarily greatly simplified in order to facilitate mathematical treatment, and a number of factors influencing transformations in metals have not been considered. It is to be noted, however, that this simple theory fits the observed experimental data very well for the latter half of the transition and with a relatively simple modification can be made to fit throughout the whole transition. The data in Tables 1 through 11 are included for the benefit of those who might wish to reinterpret the data.

Transition Rates

Based on Eq 8, values of $\log \frac{R - R_{\gamma}}{R_{\alpha} - R} - \frac{K_2(R_{\alpha} - R_{\gamma})}{(R - R_{\gamma})}$ were plotted against t as in Fig 4 for all the data in Tables 1 to 11, inclusive, values of R_{α} , R_{γ} , and K_2 being chosen to give the best straight line. This is not difficult, since the best values of R_{α} and R_{γ} can be obtained very closely

from the original data and R_{γ} is not influenced at all by K_2 . R_{α} and K_2 are somewhat interdependent but not seriously so, since R_{α} can be approximated very closely from the original resistivity data. The values R_{α} , R_{γ} , K_1 , and K_2 thus obtained are given in Table 13.

The values of R_{α} and R_{γ} are quite interesting. With only two exceptions, the values of R_{α} fall between 180 and 190 micro-ohm-cm. R_{γ} varies considerably but the values up to 58°C indicate an average value of 44 micro-ohm-cm. The variation of R_{α} with temperature is small, indicating a low temperature coefficient, while the variation of R_{γ} with temperature indicates a high temperature coefficient in the order of $60 \text{ to } 80 \times 10^{-4}$. Obviously these values are not accurate but they compare very well with observations reported in another paper.²

To see how the transition rate constants (K_1 in Table 13) vary with temperature, these data were treated according to the equation

$$K_1 = \frac{kT}{h} e^{-\frac{\Delta F^{\ddagger}}{RT}} \quad [11]$$

given by Glasstone, Laidler, and Eyring⁴, where K_2 is the specific reaction-rate constant, T is the absolute temperature, ΔF^{\ddagger} is the free energy of activation, and R , K , and h are constants. From this relation,

$$\text{Log } \frac{K_1}{T} = \text{Log } \frac{k}{h} - \frac{1}{2.3026} \frac{\Delta F^{\ddagger}}{R} \frac{1}{T}$$

Values of $\text{Log } \left(\frac{K_1}{T} \right)$ were calculated and plotted against $\frac{1}{T}$. These values are shown in Fig 5. The points follow rather closely to a straight line, the greatest deviation being shown by the 160°C point. Considering the rapidity of the transition at this temperature

FIG 5—Log (R_1/T) vs. $1/T$.

and the time required to heat the specimen, this value may be considerably in error and its deviation is not necessarily significant. As a whole, the points fit a straight line satisfactorily, and from the slope of this line the free energy of activation was calculated to be 21,200 cal per mol.

Summary and Conclusions

The change in structure and resistivity of electrolytic manganese as it transformed from ductile gamma to brittle alpha manganese was determined. The values were found to follow a typical S curve when plotted against time. The rate of change was small at first, increased to a maximum as the transition was about one-half complete, and then decreased as the transition neared completion.

Resistivity determinations proved to be the most satisfactory way to follow the transition, and studies were made at temperatures from 20 to 160°C. It was found that the transformation curve during the latter half of the transformation could be represented by

an equation based on the theory that the rate of formation of alpha manganese was determined by the amount of interface between the alpha and gamma manganese or

$$\frac{d\alpha}{dt} = K_1\alpha\gamma$$

The observed rate of formation of alpha manganese at the beginning of the transition was smaller than this theory predicted, however, and a modification of this equation

$$\frac{d\alpha}{dt} = K_1\alpha\gamma \frac{\alpha}{\alpha + K_2\gamma}$$

was found to represent the data quite well throughout the whole transition. The physical significance of this additional factor is not obvious. Apparently there are some factors operating in the initial stages of the transformation which retard the formation of alpha manganese but become less active as the amount of alpha manganese increases and are negligible during the latter half of the transition. This effect probably arises from a tendency on the part of the alpha manganese to revert to gamma manganese when the alpha-

manganese particles are small, this tendency becoming less and less as the alpha-manganese particles grow in size.

Liquid Solubility of Manganese in a Magnesium-aluminum-tin Alloy[†]

B. J. NELSON,* Junior Member, and G. F. SAGER,* Associate Member AIME

Magnesium alloy forgings offer higher and more uniform mechanical properties than heat treated magnesium alloy castings and are used principally for light weight parts that may be stressed in fatigue or subject to impact loads, or where space limitations do not permit the use of the necessarily bulkier magnesium alloy castings.

Compositions and Properties of Magnesium Forging Alloys

The nominal compositions and properties of the principal commercial magnesium forging alloys are given in Table 1.

The two that are most commonly used are AMC58S and AM65S. The former has the highest strength and is, therefore, employed for heavy duty applications. However, the forging of this alloy and of AMC57S ordinarily requires the use of slow speed hydraulic presses.

The forging alloy AM65S combines good, although somewhat lower, mechanical properties with excellent forging characteristics. This alloy can be forged on hammers, upsetters, rolls, and mechanical presses, as well as on hydraulic presses. These characteristics make it particularly useful for many applications.

Manganese Segregation in AM65S

The alloy AM65S contains 5 pct tin, 3½ pct aluminum, and a small amount of manganese, the manganese being added to insure satisfactory resistance to corrosion. Some manganese segregation was occasionally encountered in this alloy. In many applications, such

Table 1 . . . Magnesium Forging Alloys

* Yield strength is the stress at which the material exhibits a permanent set of 0.2 pct.

† Wrought alloys with the letter "C" in their designation are of controlled high purity, iron and nickel being held to less than 0.005 pct each. The same nominal compositions without guaranteed iron and nickel limits but with identical mechanical properties are available as AM57S, AM58S and AM58S-T5. The "-T5" temper is obtained by artificial aging after forging.

‡ When this investigation was started, the nominal manganese content of AM65S was 0.5 pct.

segregation is of no particular consequence, but when forgings are acid dipped prior to the application of various chemical coatings, the segregated particles of manganese constituent may stand in relief. The resultant surface roughening may impair appearance and is undesirable in forgings employed in the textile industry, where very smooth surfaces are essential to avoid the catching and breaking of fine threads. An effort was therefore made to determine the cause of manganese segregation in this alloy and find a method for its elimination.

Radiographic examination of a series of cast ingot sections and extruded samples of the AM65S type having manganese contents ranging from zero to about 0.7 pct revealed no appreciable manganese segregation when the manganese was less than about 0.4 pct. A

small amount was observed with a manganese content of 0.46 pct and considerable with manganese contents of 0.6 pct or higher.

Attempts to eliminate the manganese segregation by variations in the melting and casting conditions were unsuccessful and it soon became apparent that the trouble was attributable to the fact that the manganese contents that caused segregation were in excess of the amounts that would remain in solution at temperatures encountered in the melting and/or casting operations prior to the complete solidification of the ingots.

A knowledge of the amounts of manganese that would be soluble in molten alloys of the AM65S type at various temperatures was obviously desirable. The liquid solubilities of manganese in binary Mg-Mn alloys and in Mg-Al-Mn and Mg-Zn-Mn alloys have been determined by Tiner and others,* but no data on the solubility of manganese in molten magnesium alloys containing tin and aluminum are given in the literature. For this reason, an investigation to determine the solubility of manganese in a magnesium alloy containing 5 pct tin and 3.5 pct aluminum (AM65S type) was undertaken.

† Except for the variations in manganese content, this alloy corresponds to the American Magnesium Corporation Alloy AM65S or A.S.T.M. alloy TA54.

FIG 1—Manganese contents of molten AM65S as a function of holding time.

Liquid Solubility Determinations

The settling procedure was selected as the most suitable method for determining the solubility of manganese in alloys of the type under consideration. Briefly, this method involved saturating the alloy with manganese at a temperature substantially above that at which the solubility was to be determined, then cooling the melt to the latter temperature and holding it at that temperature for a substantial period of time. Samples for analysis were carefully ladled from the upper portion of the melt at hourly intervals during the aforementioned holding period. After the ladling of each sample, the melt was stirred to redistribute some of the manganese that had already settled, because it appeared that when the latter particles of manganese again settled, they aided in carrying down more of the manganese and thus hastened the attainment of equilibrium.

The melts were prepared and held in a No. 8 Tercod crucible holding approximately 4 lb of metal. The manganese was added either in the form of a prealloyed ingot (Dow M) containing about 1.5 pct manganese or by the use of a flux (Dow 250) containing man-

ganese chloride. In calculating the flux additions, it was assumed that the manganese introduced would be equal to 22 pct of the total weight of the flux. Temperatures were measured with an iron-constantan thermocouple enclosed in a seamless steel tube, the lower end of which was welded shut. This protection tube also served as a stirring rod. The samples ladled from the upper portions of the melts at the various intervals were analyzed for tin, aluminum, manganese, and iron. Table 3 shows the complete analyses for manganese, tin, aluminum and iron, together with the limiting solubilities of manganese used in drawing the solubility curve.

These manganese contents are plotted as a function of the holding time in Fig 1. It will be noted that the curves become nearly horizontal when the longer holding periods are reached, indicating that the manganese contents are approaching the equilibrium values for the various holding temperatures.

The solubility of manganese so determined at various temperatures is plotted in Fig 2. In general, the points fall on a fairly smooth curve and indicate that the solubility of manganese increases from about 0.45 pct at 1200°F to approximately 1.32 pct at 1500°F.

FIG 2—Solubility of manganese in molten AM65S.

The value for the lowest temperature (1150°F) is somewhat lower than that which would be predicted from an extrapolation of the main portion of the curve to this temperature. One possible explanation of this deviation would be the existence of a "quaternary peritectic" at a temperature between 1150 and 1200°F.

Considerable difficulty was encountered in obtaining consistent equilibrium values for the manganese solubility at temperatures near 1400°F. It was suspected that the trouble might be attributable to small variations in the aluminum contents of the alloys. In order to check this hypothesis, settling tests were conducted on alloys containing several slightly different amounts of aluminum. The results of these tests are shown in Fig 3. These results indicate that the solubility of manganese in alloys of the type under discussion decreases markedly and almost linearly with increasing aluminum contents.

While the above effect of aluminum on the solubility of manganese might be due merely to the decrease in the solubility of one element with increasing concentrations of a second solute, it was suspected that a compound containing both aluminum and manganese might be precipitating. This would, of course, result in a concentration of aluminum as well as man-

ganese at the bottom of the melts. In order to check this point, an AM65S melt containing 1.2 pct manganese was prepared in a tapered graphite crucible. After heating to a temperature of 1550°F, the melt was cooled and held for 3 hr at a temperature of 1350°F. In order to avoid complications that might be introduced if iron dissolved from the thermocouple protection tube, temperatures were measured by a thermocouple wired to the outside of the crucible. At the end of the three-hour holding period, the crucible was removed from the furnace and cooled by a fine spray of water directed on the bottom until freezing was complete. Fig 4 shows the macrostructure of a section of the solidified melt adjoining the bottom of the crucible. The concentration of manganese constituent at the bottom is plainly evident. Analyses of the bottom zone and the main portion of the melt gave the following results:

| Location | Per Cent | | | |
|--------------------|----------|------|------|-------|
| | Al | Sn | Mn | Fe |
| Main portion . . . | 3.17 | 4.82 | 0.50 | 0.001 |
| Bottom | 5.83 | 4.99 | 4.62 | 0.10 |

FIG 3—Effect of aluminum content on solubility of manganese in alloys of the AM65S type at 1350°C.

It will be noted that the amounts of aluminum, manganese, and iron in the bottom zone are substantially greater than those in the main portion of the melt.

Effect of Manganese on Tensile Properties and Resistance to Corrosion

It is obvious that manganese is likely to precipitate and segregate in AM65S melts if the manganese contents of these melts exceed the values indicated in Fig 3 for temperatures corresponding to those involved in the melting and casting of such melts. This naturally raises a question regarding the possible effect on mechanical properties and resistance to corrosion of decreasing the manganese to a value at which precipitation and segregation of that element are not encountered.

Tensile tests conducted on as-extruded, press forged and hammer forged samples of AM65S type alloys having various manganese contents ranging from zero to 0.66 pct gave the results shown in Table 2. The manganese content of the alloy can be

reduced to approximately 0.2 pct without impairing tensile properties. However, complete elimination of the manganese causes substantial reductions in the tensile and yield strengths.

Accelerated and atmospheric corrosion tests conducted on extruded samples of AM65S type alloys having various manganese contents showed that the manganese content could be lowered to about 0.2 pct without impairing resistance to corrosion. However, the complete elimination of the manganese impaired this characteristic to a significant extent.

Conclusions

1. The solubility of manganese in

molten AM65S alloy increases with temperature from a value of about 0.45 pct at 1200°F to 1.32 pct at 1500°F.

2. The manganese solubility at a given temperature decreases markedly with increasing aluminum content.

3. Manganese segregation in the alloy can be controlled by maintaining the manganese content below the amount soluble at the lowest temperatures encountered in the melting and casting of the alloys.

4. The manganese content can be lowered to a sufficient extent to avoid appreciable segregation without impairing tensile properties or resistance to corrosion, but the complete elimina-

tion of the manganese would adversely affect both the strength and the resistance to corrosion.

Acknowledgment

The authors express their appreciation to the Aluminum Company of America for permission to publish this work. They also express their appreciation of the constructive guidance and advice of Dr. Wm. L. Fink, under whose supervision the investigation was carried out and to Mr. Richard Patz, who assisted in the preparation and sampling of a number of the melts.

The Comparative Creep Properties of Several Types of Commercial Coppers

A. D. SCHWOPE,* Junior Member, K. F. SMITH,* and L. R. JACKSON,† Member AIME

Burghoff and Blank¹ have pointed out that the creep properties of hard-drawn coppers are closely associated with their individual softening characteristics and have further shown that the creep resistance of various types of copper is improved, under certain circumstances, by cold stretching.

In the design of certain types of electrical machinery, it is important to have the creep resistance as high as possible; furthermore, short-time creep strength is important since in many cases stresses are large only during warming-up and cooling-down periods.

In this paper, data are presented showing the effect of cold work on the short time creep strengths of various types of commercial copper under several conditions. It is shown that trends from short-time creep tests are evident at longer times.

Materials Used in the Investigation

The coppers used in this investigation were commercial grade and of two basic types, oxygen free high conductivity (OFHC) and tough pitch. Additions of silver in amounts of 15 and 25 oz per ton were added to each of the two coppers. The analyses of these six coppers are given in Table 1. Originally, they started as wire bars 4 × 4 × 54 in.

A square rod was made by hot rolling the wire bars to 1/16-in. rod in 8 passes. This rod was then cold drawn to 0.445-in.-diam rod and annealed for 3 1/2 hr at 1000°F. It was then cold drawn to 0.325-in. rod and again annealed at 1000°F for 3 1/2 hr. Hard square rods were then made by cold rolling to 0.257 × 0.257-in. rod. Soft wire was made from the hard-

drawn material by annealing at 650°F for 3 hr.

The final rolling was performed using a set of 9-in. grooved rolls revolving at 30 rpm, which produced square wires. Reductions of approximately 5, 20, 30, and 40 pct were obtained using several passes in the same direction for the large reductions.

The 5 pct reduction by drawing was accomplished using a steel die having 2 parallel bearing surfaces. The die angle was 7 1/2 degrees and the wires were lubricated with a paste of ceresin wax dissolved in carbon tetrachloride. The speed of drawing was 13 fpm. Since work was done on only two sides of the wire simultaneously, it was necessary to rotate it 90 degrees each pass to insure uniform deformation.

The room-temperature tensile properties of the various tempers are given in Table 2. The grain size of the an-

nealed 0.257-in. wires was uniform and averaged about 0.035–0.045 mm.

Experimental Procedures for Short-time Creep Tests

Standard creep-test frames (Fig 1) were used for the testing. Special fixtures were designed to apply axial compressive and tensile loads to the copper wires. The compression specimens were 1 in. long and the ends were ground flat and parallel. The creep in compression was indicated by the movement of reference marks scratched on intersliding platinum strips attached to the moving heads of the fixture. The movement was measured with an optical micrometer fitted with a filar eyepiece on which the smallest division was 0.00005 in.

The tensile creep specimens were 4 in. long which provided ample gripping surface for the jaw-type grips. The platinum strips were attached to a one-inch gauge length of the wire and the creep measured as previously described.

The single-specimen furnaces were connected to individual power and control sources. The controlling equipment consisted of Foxboro controllers

specially fitted with anticipating thermocouples which controlled the temperature to less than 3°F of the control setting which was 572°F (300°C). Two thermocouples were mounted on each specimen, one to the controller and the other to the recorder and potentiometer for measuring the temperature.

The specimen was mounted in its fixture and placed inside the furnace and assembled in the test frame. The furnace was brought up to temperature, with a zero load on the specimens, in approximately 30 min. A no-load reading was taken and the load applied by means of dead weights on the lever arm. Readings were taken thereafter at suitable intervals and the test continued until a secondary or minimum creep rate was well established. The tests averaged twenty-four hours in duration.

Discussion of Results

The results of these tests are summarized in Table 3, which lists the creep stress, initial deformation, total creep, minimum creep rate and the total time of test. The initial deformation is seen to vary only slightly among the various coppers for similar degrees of cold work. Total creep is defined as the total strain minus the initial strain. The initiation of the third or rapid stage of creep is indicated in the table, with its approximate time.

* Stress at 0.2 pct offset from initial slope of stress-strain curve.

Typical of the types of curves obtained are those shown in Fig 2 comparing various degrees of cold work. Although the hardness and the strength properties of the wires increased as the per cent reduction by cold work increased, the creep rates are not so simply affected. It is normally supposed that as the strength properties increase, the creep properties, such as rate and total deformation, are benefited. This can be considered true only as long as some competing process does not set in. As was pointed out by Burghoff and Blank, recrystallization,

as manifested by softening, takes place when the strained metal is heated within a critical temperature range and the creep rate thereby increased. In a previous paper,² the relation between degree of cold work and the course of recrystallization for most of the coppers used in this investigation was described. It was pointed out that as the cold work increased, the temperature for softening decreased, or in isothermal annealing, the softening time decreased.

It is important, then, in analyzing creep data to keep in mind that recrystallization and creep are taking place simultaneously. Thus, in Fig 2 the curves for 5 pct cold-rolled OFHC copper appear to be normal, having progressed into the constant creep-rate stage. However, the wires rolled 20, 30, and 40 pct show decidedly different characteristics. It is evident that the beginning of the stage of rapid or acceleration creep occurs sooner as the creep stress and the degree of cold work increase.

Since softening is occurring simultaneously with creep, it is reasonable to expect the yield strength to decrease from the cold-worked value to that of soft material during testing. The majority of these creep tests were made using stresses higher than the yield strengths of the soft material so that at some time during the tests the yield stress must equal the applied creep stress. When this occurs, it is postulated that the third or final stage of creep should be initiated.

Utilizing the relations set forth in a previous paper,² the time for the yield strength to drop to the applied creep

stress can be approximated. The detailed calculations are given in Appendix A. The arrows on the creep curves indicate these computed times. Fair agreement between calculated and actual points of inflection is observed. It is to be emphasized that this relation is an empirical approximation which enables the engineer to choose a suitable degree of cold work for a particular temperature application. This relation is most effective at low amounts of cold work where the yield strength has not been appreciably changed or at temperatures where it is little affected.

Tension vs. Compression Creep

The majority of the compression creep tests covered only small ranges of strain and only in the cases where

the third stage of creep set in, did local instability occur. Typical of the curves obtained are those shown in Fig 3. Tension and compression creep are compared in Fig 4 and 5.

It will be noted that the creep rate in compression is markedly higher than that for tension. In cold-drawn or cold-rolled materials, as were used here, this difference may be connected with the Bauschinger effect.

CREEP IN COLD-DRAWN VS. COLD-ROLLED MATERIALS

From Fig 4 and 5, it will be noted that in general, the cold-drawn material has a higher creep rate under comparable conditions than the cold-rolled material. This effect is probably connected with the manner in which the two methods of cold deformation distribute the cold deformation

throughout the cross-section of the material. Fig 6 shows the results of a Knoop hardness transverse through drawn, rolled, and annealed tough-pitch copper. It will be noted that while the drawn material is harder at the outside, the rolled material is harder at the center. The area under the hardness curve is about 5 pct greater for the cold-rolled material than for the cold-drawn. It will also be noted from Table 2 that the yield and tensile strengths are, in general, slightly higher for the rolled than for the drawn material. These two factors probably account for the differences in creep rate observed. The nonuniformity in strain hardening evident in Fig 6 for the 5 pct cold-worked wires persists in the wires rolled 40 pct.

EFFECT OF SILVER ON CREEP PROPERTIES

It is well known that silver added to copper increases the resistance to recrystallization. Likewise, it might be expected that it should have a similar effect on the creep properties of cold-worked material. Qualitatively, this is true, but quantitatively, the relation is not simple. Fig 7 shows the recrystallization curves of the various coppers. These results are based on the fractional change in yield strength of hard drawn (84.4 pct reduction in area) 0.081-in. wire, annealed for 1 hr at various temperatures. There is little difference among the silver-bearing coppers, as far as the recrystallization curves are concerned.

The effect of silver on the secondary creep rate is illustrated in Fig 8. It is evident that silver, while effective in reducing the creep rate of both tough-pitch and OFHC coppers, does not equalize the two types as it did in the softening properties. Although the effect of silver is comparatively small at low amounts of cold working, it is very active at greater cold reductions. Its effectiveness is manifested in the delaying of the third stage of creep.

Long-time Creep Tests

During the course of this investigation, long-time tensile creep tests (>1000 hr) were performed on commercially drawn (0.081 in.) wires of tough-pitch, OFHC, and OFHC plus 15 oz of silver per ton, coppers. Three commercial tempers were included in these tests; annealed, half hard (37.1 pct red. in area), and hard drawn

Arrows indicate recrystallization has reached critical stress level.

FIG 3—Time-compression curves at 572°F for various coppers cold rolled 5 pct.

(84.4 pct red. in area). An additional temper, 10 pct cold worked, was produced by pulling annealed wire in tension until the desired deformation was produced. The room-temperature tensile properties are given in Table 4.

These tests were carried out at lower temperatures and higher stresses than the short-time tests. The details of the creep tests are given in Table 5. Typical creep curves for the three coppers are

shown in Fig 9, 10, and 11. The results of these tests are consistent with the short-time tests, although in some instances the effects of cold work and silver are greater than in the short-time tests.

The long-time tests serve to establish more firmly an optimum degree of cold work for each temperature and the beneficial influence of silver on the creep properties of copper. It will

be observed that the long-time tests rate the various coppers in the same order as the short-time tests.

The comparative data on creep rates of OFHC and tough-pitch copper in Table 4 appear to be at variance with the results of Burghoff and Blank, who found little difference between the creep rates of some OFHC and ETP copper both in the annealed and cold-drawn condition. It should be pointed

out, however, that these authors also found little difference between the softening characteristics of the two lots of copper they used in this investigation.

Summary

The effect of cold work on the creep characteristics of tough-pitch

and OFHC coppers, unalloyed and silver bearing, has been determined for temperatures from 200 to 572°F. The most important results are:

1. Cold work increases the creep strength of copper; however, the benefit from cold work is lost at temperatures where recrystallization is rapid. This temperature varies with the

amount of cold work and the type of copper.

2. The addition of silver to either tough-pitch or OFHC copper raises the temperature at which rapid recrystallization occurs; the effect is approximately the same on both types of copper.

3. While additions of silver effec-

tively lower the creep rate of both tough-pitch and OFHC copper as cold worked, the silver-bearing OFHC copper has a markedly lower creep rate than comparable tough-pitch copper.

Appendix

In a previous paper, an equation was presented by which the process of recrystallization, as evidence by softening, could be charted at low temperatures—long-time from short-time high-temperature tests. The validity of this relationship has been shown and useful curves derived by its application. The equation

ln t = ln ln (1 / (1 - x)) - A + Q / RT

in which the terms for tough pitch copper, cold worked 5 pct, and under creep test at 300°C and 10,000 psi (Fig 3) are

t = time in hours for the yield strength to drop to 10,000 psi.

x = fraction recrystallized corresponding to a drop in yield strength to 10,000 psi.

A = a constant = 22.5 for tough pitch, taken from Fig 6 of the reference paper. (Table 6).

Q = energy of activation = 30,000 cal per mol.

R = gas constant = 1.99 cal per degree per mol.

T = temperature, degrees Kelvin = 573°K.

This equation solved for t yields a value of 21 hr at which time the yield

The Rapid Determination of Orientations of Cubic Crystals

C. G. DUNN,* Member AIME and W. W. MARTIN†

Introduction

Various X ray diffraction techniques have been developed for determining orientations of crystals. Transmission and back-reflection Laue methods^{1,2,3} in particular have been found to be very useful. In many applications, however, a need still exists for a simplification of the details of analysis so that orientations can be determined more rapidly, and operators with little or no training in crystallography can be easily instructed in the necessary procedures.

Filling this need in part is a system of analysis that has been in use for several years in the Metals Section of the Laboratory, General Electric Co., Pittsfield, Mass. This method is an extension of the one of Majima and Togino,⁴ which uses fifty-five indexed standard transmission Lauegrams to cover the entire range of crystal orientations. Greater rapidity in determining the orientation of a crystal is achieved by using a slightly larger set of standard Lauegrams and by systematizing the steps followed. This system of analysis in its present form constitutes the subject matter of the present paper. Although the method uses transmission X ray Laue patterns, many of the operations are applicable to the analysis of back-reflection Lauegrams.

Very briefly the method is based on the fact that Bragg and azimuthal angles for two or more identified Laue diffraction spots completely determine the orientation of a crystal, and standard Laue photographs of the Majima and Togino type provide a ready means for identifying Laue spots. After a preliminary analysis, which consists of identifying the pattern in terms of one of the standard patterns, a correctly marked Lauegram is selected to carry out the final analysis. From measured Bragg and azimuthal angles, the normals (poles) of the reflecting planes for the selected Laue spots are located on a stereographic projection and the orientation of the crystal determined (in terms of the positions of cube poles for

example) by a few additional operations on a Wulff net.

The actual procedure followed will be illustrated in detail after a brief treatment of X ray problems connected with orientation determinations and a discussion of useful principles and techniques.

X Ray and Plotting Problems

RELATIVE ADVANTAGES OF BACK-REFLECTION AND TRANSMISSION LAUE DIFFRACTION METHODS

In the back-reflection Laue method

it is easy to make a direct measurement of the tilt of a zone of Laue spots. Specimen thickness also is generally no problem. In the case of thin specimens, however, the time of exposure is less for the transmission Laue method. For example, with silicon ferrite this advantage holds up to a thickness of 0.6 mm if tungsten radiation at 40 kv peak voltage is used. Furthermore, the transmission photograph represents the entire thickness of the crystal whereas the back-reflection picture represents only a surface layer (a thickness of less than 0.05 mm for silicon ferrite), the deeper layers supplying a negligible amount to the diffraction pattern. If a crystal is distorted, the transmission Laue pattern gives more information particularly with regard to the orientation of the crystal and the overall amount of spread in orientation. Finally a $3\frac{1}{4} \times 4$ in. film suffices for transmission photograms; a 4×5 in. or 5×7 in. film with a central hole is needed for back-reflection patterns. Not only is the manipulation of film easier because of the size of film, but

¹ References are at the end of the paper.

there is also less work involved in camera loading with film requiring no central hole.

AIDS FOR THE LAUE METHOD

A convenient method for mounting flat specimens is shown in Fig 1. A collimating tube is joined centrally to a 5 in. square steel plate with the rear pinhole flush with the surface. An adjustable clamp to provide vertical and horizontal movement of the sample without rotation rests on the square plate in such a way that its upper edge is always 90° to a line passing from the rear pinhole to the long pin located near the top of the large plate (see Fig 1). The purpose of this pin is to transfer a reference direction directly to the film in the form of a pin-prick and thereby solve the alignment problem for measuring azimuthal angles. The specimen shown in Fig 1 is held in position by one clamp and two Alnico magnets. Larger specimens can be held with auxiliary clamps or with scotch tape. Further, the camera shown in Fig 1 can also be used as a specimen holder for a back-reflection camera.

RELATIONS FOR PLOTTING THE POLE OF A PLANE

The positions of poles of planes that appear in stereographic projection depend on which surface of a flat specimen is used for reference. Our procedure is to use the surface which is visible when the sample is mounted for X ray-ing, either for transmission or back-reflection photography (as shown in Fig 1). Fig 2 diagrammatically shows the position of the normal *N* to a plane which diffracts X rays to a point *L* on the film. The normal *N* makes an angle δ with the surface of the sample, and the diffraction spot *L* makes an azimuthal angle ϕ with the reference direction, *R.D.* The distance *r* from the central image *O* to the spot *L* is given by Eq 1:

$$r = D \tan 2 \delta^* \tag{1}$$

where *D* is the distance between specimen and film.

The incident beam, the diffracted beam, and the normal to the reflecting plane, lie in a plane which intersects the film along the line *OL* at an angle ϕ to the reference direction of the sample. This relationship also determines ϕ for plotting the pole of the plane in stereographic projection. The distance *r* determines the value of δ according to

* A similar equation holds for back-reflection, the angle δ being replaced by $90^\circ - \delta$.

FIG 2—Schematic diagram showing angular relations for the Laue method.

FIG 3—Schematic diagram showing correct relation for film, specimen, and stereographic projection.

The point *A* locates the direction of the pole of the plane which reflects X rays to the point *L* on the film.

Eq 1; therefore, a direct reading net can be easily made for measuring δ . Later a photograph will be shown of an arrangement for holding the film and measuring δ and ϕ directly (it is called a δ, ϕ analyzer).

To keep relationships correct during analysis the film is held so the observer looks through the film onto the surface of the sample. This applies to both transmission and back-reflection work. Fig 3 showing specimen, film, and the plot of one pole in stereographic projection illustrates this for transmission. As in Fig 2, the pole of the reflecting

plane is diametrically opposite the Laue spot.* Its distance from the basic circle, which coincides with the plane of the sample, is δ degrees measured along a diameter. The basic circle and two diameters of a Wulff net are properly graduated for making this plot. The meridian and latitude lines of the Wulff net are also indispensable for plotting crystallographic directions from the known angular relationships between planes. Therefore, the plot is

* In back-reflection work the pole of the reflecting plane and the Laue spot fall on the same side of the incident beam.

most conveniently carried out on tracing paper superimposed on a Wulff net.^{5*}

In a Laue photograph certain groups of diffraction spots lie on conic sections (ellipses, parabolas, and hyperbolas). Such groups are called zones. In stereographic projection poles of planes for a zone fall on a meridian line when the plot is correctly rotated about the center of the Wulff net (in space they lie in a common plane). The direction 90° away (and this will fall on an equator when the poles of the zone are superimposed on a meridian line) is the zone axis of the zone. When a zone axis is within 45° of the center of projection, the zone of Laue spots on the film is an ellipse; when a zone axis is at 45°, the zone is a parabola; and when a zone axis is beyond 45°, the zone is a hyperbola. In back-reflection Laue photographs all zones are hyperbolas.

Crystallographic Relationships in Cubic Crystals

ANGLE BETWEEN PLANES

The angle θ between two planes $(h_1k_1l_1)$ and $(h_2k_2l_2)$ or two directions $[h_1k_1l_1]$ and $[h_2k_2l_2]$ can be calculated from Eq 2 when the Miller indices are known.

$$\begin{aligned} \cos \theta = & \frac{h_1h_2 + k_1k_2 + l_1l_2}{\sqrt{(h_1^2 + k_1^2 + l_1^2)(h_2^2 + k_2^2 + l_2^2)}} \quad [2] \\ \text{when } h_1h_2 + k_1k_2 + l_1l_2 = 0, \theta = 90^\circ. \end{aligned}$$

ZONE AXIS

$$\begin{aligned} \text{Since } h_1u + k_1v + l_1w = 0 \\ \text{and } h_2u + k_2v + l_2w = 0 \\ \text{when } \begin{cases} u = a(k_1l_2 - k_2l_1) \\ v = a(l_1h_2 - l_2h_1) \\ w = a(h_1k_2 - h_2k_1) \end{cases} \quad [3] \end{aligned}$$

(where a is a suitable constant to make u, v , and w small integers) the direction $[uvw]$ is 90° from the directions $[h_1k_1l_1]$ and $[h_2k_2l_2]$, which are the poles of planes $(h_1k_1l_1)$ and $(h_2k_2l_2)$ respectively since the system is cubic. The line of intersection of the planes $(h_1k_1l_1)$ and $(h_2k_2l_2)$ is the direction $[uvw]$.

$$\begin{aligned} \text{Also } h_iu + k_iv + l_iw = 0 \quad [4] \\ \text{when } \begin{cases} h_i = mh_1 + nh_2 \\ k_i = mk_1 + nk_2 \\ l_i = ml_1 + nl_2 \end{cases} \text{ for any integral values of } m \text{ and } n. \end{aligned}$$

Consequently, the direction $[uvw]$ makes an angle of 90° with all direc-

tions of the form $[h_ik_il_i]$ and, therefore, is the zone axis of all planes $(h_ik_il_i)$. Example: starting with Miller indices $\bar{1}, 0, 1, 1, \bar{1}$, and 0 for h_1, k_1, l_1, h_2, k_2 , and l_2 respectively and using values of 3 and 2 for m and n respectively, we obtain $[111]$ for the zone axis of the $(\bar{1}01)$, $(1\bar{1}0)$, and $(1\bar{2}3)$ planes.*

The Relationship between Film Nets and Stereographic Projection Nets

When poles of planes for a zone are plotted in stereographic projection, points are obtained which fall on a meridian line. Also, if the direction of plotting is reversed, a meridian line of a Wulff net becomes a conic section on a film net. Let us call the conic section thus obtained, however, a zone or meridian line on a film net. Similarly a latitude line of a Wulff net can be plotted to obtain a latitude line of a film net. The reverse plotting must be carried out according to whether the net is to be used for transmission Lauegrams or back-reflection Lauegrams. Using an arrow to indicate the operation of plotting, the following relations can be indicated for well known nets.

| Film Net | Projection Net | Use of Film Net | Lit. Ref. |
|--|---|----------------------------|-----------|
| Greninger \rightleftharpoons | Wulff net | Back-reflection Laue | 3b |
| Leonhardt zero-tilt \rightleftharpoons | Wulff net | Transmission Laue | 6 |
| Leonhardt 90°-tilt \rightleftharpoons | Polar net | Either B.R. or Trans. Laue | 6 |
| Leonhardt w -tilt \rightleftharpoons | Intermediate net between Wulff and Polar net. | Transmission Laue | 6 |

Fig 4 shows one-half of a Leonhardt zero-tilt net;⁶ the dotted curves spaced at 10° intervals are meridians and the solid line curves spaced at 5° intervals are latitude lines. The distance D satisfies Eq 1, r becoming equal to D when δ equals 22½°. An illustration will be given later showing how angles between planes can be obtained with this net upon placing a zone of Laue spots on a meridian (by interpolation) and reading differences in latitude between Laue spots.

Fig 5 shows a new diagram that we have developed and which we shall call an isogonal net because each curve represents a constant angle from a point on the base line—the straight line graduated in 5° intervals. The net is a combination of tilted Leonhardt curves (w equal to 5, 15, and 25°) with no meridian lines and with two

sets of latitude lines. One set gives the 45, 90, and 135° differences in latitude, the other set the 30, 60, 90, and 120° differences in latitude measured from correct points on the base line. The base line must be used for all measurements of angle between planes except those of a zone. In this particular case, as will be illustrated later, the angles between planes for a zone can be read directly when one Laue spot of a zone is placed on the base line.

The Greninger net has been adequately described elsewhere. An illustration, however, using such a net will be given later.

The film net shown in Fig 6 is very useful for plotting poles of planes and directions of zone axes in stereographic projection. When used for these purposes, however, the net must be coupled with a scale for measuring the azimuthal angle ϕ . The angle δ for any Laue spot can be read from the polar scale which is drawn in half circles. The tilt of a zone measured from the center of projection can be read directly from the net when the zone of Laue spots is correctly located by interpolation among the zones of the net. Unlike the zones of the Greninger net, however, the accuracy of measure-

ment of tilt falls off rapidly near 90° and the position of Laue spots in the direction of the zone axis must be used for an accurate determination of the tilt of the zone.

Standard Laue Photographs

For several years Majima and Togino standards, which were re-indexed for simplicity of analysis as will be described later, were used for identifying Laue spots and zones of Laue spots. Experience thus gained indicated a need for a larger set to cover all possible orientations more uniformly; so 75 patterns were made and these were prepared in two sets—one for *preliminary analysis* and the other for *final analysis*.

In all 300 patterns were made for the body-centered cubic lattice and the face-centered cubic lattice. However, it is not the purpose of this paper

* This article, incidentally, gives an excellent treatment of the properties and uses of a Wulff net.

* Standard projections (see Ref. 1) can also be used to determine members of a zone and the zone axis.

to present all 300 patterns in full size reproduction; rather the aim is to illustrate how such patterns may be used for rapid analysis.

COORDINATES OF STANDARD LAUE PATTERNS

The two angular coordinates to be considered now and discussed in relation to Fig 7a and 7b locate only the crystallographic direction that is parallel to the incident X ray beam. They are not sufficient to determine the orientation of a crystal because rotation about the X ray beam as an axis is still indeterminate.

Fig 7a shows diagrammatically the angles α and β used by Majima and Togino with their standard Laue patterns and the angles α and β' used by the present authors with a new set of standards. The relationship between β and β' is

$$\tan \beta' = \cos \alpha \tan \beta \quad [5]$$

When α and β are zero, β' is also zero and the X ray beam is then normal to a cube plane.

The stereographic projection can be treated in two ways to show the angles

α and β' . One way makes use of the unit stereographic projection triangle (see Fig 7b) formed by the [100], [110], and [111] directions of orientation A, which is plotted in terms of cube poles. The values of α and β' are zero for orientation A. Now any crystallographic direction P whatsoever may be found in the unit triangle and its position determined by two angles α and β' if we understand that the direction P is actually to be brought to the center of projection. The coordinates of P, which may be given by α and β' , then specify the crystallographic direction which coincides with the incident X ray beam. Suppose P is brought to the center of projection by two angular rotations—one of α degrees about a vertical axis in the plane of the paper, the other of β' degrees about a horizontal axis in the plane of the paper. Expressed in terms of cube poles, the final orientation is C and the intermediate orientation after the α -rotation is B. On the Wulff net, α gives the change in longitude whereas β' gives the change in latitude of point P during this rotation of A to C.

The unit triangle will be used again later.

The second way of determining α and β' for orientation C is given simply as follows: place the outermost cube pole on an equator of a Wulff net and read directly the angles α and β' , which are determined entirely by the cube poles of orientations C and A as indicated in the figure. This relationship, incidentally, provides a quick and convenient check of the analysis made with the aid of a standard Laue pattern.

Similarly α and β may be found in two ways from the stereographic projection. First if the coordinates of P are expressed in terms of meridian intercepts on two diameters at 90° as shown, the angular distances to the center of the projection are α and β . Secondly, they can be found from the cube poles of the orientation C by constructing a diameter through the correct cube pole and locating its point of intersection in the corresponding {100} plane. Actually no diameter need be drawn when the plot is on tracing paper because the equator of a Wulff net becomes the desired diameter upon placing the correct cube poles on a meridian line.

In the unit stereographic projection triangle, a point indicates that crystallographic direction which is parallel to the incident X ray beam. Directions for the Majima and Togino set of standards, which are 0,0; 5,0; 5,5; etc. to 45,45 in α , β units, are shown in the unit triangle form in Fig 8a. Each direction falls at the center of a circle of 2° radius. These circles, forming horizontal and vertical rows, fall on meridian lines. Positions of the new standards (see Fig 8b) were chosen so that horizontal rows would fall on latitude lines and the coverage of the unit triangle would be generally both complete and uniform. Some points, which are marked with central black dots, did not fit into the otherwise regular scheme. Inaccuracies in both Fig 8a and 8b are due largely to the errors in the enlarged Wulff net, which was used to make the plots. Results for the crystallographic directions for the new set of standards in α , β' coordinates are given in Table 1, each position in the table corresponding to a similar position in the triangle in Fig 8b.

PREPARATION AND NATURE OF NEW STANDARDS

A small experimental error occurred

FIG 7—Schematic relationship showing direction of incident X ray beam on a cubic crystal.

(a) Three dimensional drawing showing the angles α , β , and β' .

in obtaining Lauegrams for crystals oriented as outlined in Table 1; so the actual coverage represented by final standards is somewhat poorer than that indicated in Fig 8b. Nevertheless, the error is generally less than one degree, and this has little effect on the usefulness of the standards. The Laue photographs were taken on Kodak type K X ray film without any intensifying screen, using tungsten radiation at 40 kv (higher voltages introduce additional Laue spots—see later note). The distance between film and sample was 3.2 cm. Three crystals of silicon ferrite each 0.2 mm (0.008 in.) thick were used to obtain 75 patterns for the body-centered cubic lattice. No crystal rotation about an axis perpendicular to the X ray beam exceeded 20°. Exposure times were one hour, and the weaker Laue spots were well recorded. One crystal of aluminum 0.4 mm (0.015 in.) thick was used to obtain all 75 Lauegrams for the face-centered cubic lattice. Exposure times were 15 min. for the aluminum crystal.

Lauegrams obtained on $4\frac{1}{2} \times 5$ in. film and with dark Laue spots on a relatively clear background are called the original positives. From them, marked negatives $3\frac{3}{4}$ in. \times $3\frac{3}{4}$ in. in size were made as follows: first a correctly marked piece of tracing celluloid was superimposed on the positive and the composite was then printed on contrast process ortho film; secondly, this procedure was repeated using another type of celluloid tracing but the same original

(b) Stereographic projection for X ray beam in the center of projection and the crystal in orientation C , showing the angles α , β , and β' in relation to orientation A .

positive. In this way 300 negatives, to be used in making final positives on commercial ortho film,* were obtained from the 150 original Lauegrams. Except for the very intense Laue spots, which became enlarged in the reproduction process, final positives made on film were good duplicates of the original Lauegrams.

Sets of standards for preliminary analysis may be mounted between large glass plates in the arrangement partially shown in Fig 9 and 10 for the body-centered (set *B*) and face-centered (set *F*) lattices respectively. Here the positions correspond to those in Fig 8b, and individual patterns have the (010) Laue spots along a vertical line above the central image. The [111] and [001] zones of set *B* and the [101] and [001] zones of set *F* are marked in lightly to show con-

tinuity of the pattern with rotation of the crystal and to aid somewhat in the more rapid scanning of the group while locating the pattern which is similar to the one being analyzed.

Standards of the second set for use in the final analysis are kept individually in an index file and are marked so that steps to be taken in the analysis are nearly self-evident. Illustrative examples of such standards are shown in Fig 11 to 16. Miller indices for a zone of Laue spots (the zone axis) are enclosed in brackets and located near the zone; those for a Laue spot (the reflecting plane) are located adjacent to the Laue spot. During the final analysis when the angles δ and ϕ are to be measured, the correct standard is taken from the file and superimposed on the film being analyzed. The identification of zones and Laue spots to use are determined quickly in this way, and zones or Laue spots on films do not have to be marked.

(a) (above) The 55 directions used by Majima and Togino in obtaining standard Lauegrams.
(b) (below) The 75 directions used by the authors in a new group of Lauegrams.

In using standard 1-1 of set *B* shown in Fig 11, it is important to know that the poles of the (031) and ($\bar{0}\bar{3}1$) planes fall $143^{\circ}8'$ apart (according to Eq 2). Halfway between them is the pole of the (001) plane. The (010) pole lies on the same meridian 90° from the (001) pole. The [100] direction, the zone axis of the (031) and ($\bar{0}\bar{3}1$) planes, lies 90° away, a point easily located with the aid of a Wulff net. The tilt of the (100) plane obtained this way, however, is not accurate; so the pole of the ($\bar{3}01$) or the pole of the (301) plane should be used to determine the tilt. The [301] direction for example is between the [001] and [100] directions, $18^{\circ}26'$ from the latter. The [111] zone, which is also marked, need not be used except as a check.

The steps of analysis using standard 1-1 of set *F* are the same as those for 1-1 of set *B*. However, the strong $\langle 101 \rangle$ zones, which may be used for checking purposes, can be used very conveniently alone if desired to make the complete analysis.

A very simple procedure for carrying out an analysis, which applies to most standards, can be illustrated

FIG 9—Laue patterns of the body-centered cubic lattice for determining $\alpha\text{-}\beta'$ in a preliminary analysis.

with standards 29-15 shown in Fig 13 and 14. Plot three poles from the [001] zone including the (010) and ($\bar{1}\bar{1}0$) poles if the Laue spots show on the film. Finally, to complete the analysis in terms of cube poles, plot the (001) and (100) poles with the aid of a Wulff net.

In other Laue patterns which do not contain the (010) or the ($\bar{1}\bar{1}0$) Laue spot, the procedure of analysis is only slightly modified. Standards of the type illustrated in Fig 15 and 16 (crystals are in the threefold symmetry position) are examples. The poles of the ($\bar{1}30$) and ($3\bar{1}0$) planes for the [001] zone, referring to Fig 15, are $126^{\circ}52'$ apart (according to Eq 2); halfway between them is a (110) pole, and this serves to locate the (010) and (100) poles which belong to the [001] zone. The [010] zone need not be used except as a check on the analysis. The {111} poles are sometimes useful

in making an analysis; so {111} Laue spots are marked on some standards. Similar in procedure for analysis is the use of the standard shown in Fig 16. The ($\bar{1}20$) and ($2\bar{1}0$) poles, in this case, fall $143^{\circ}8'$ apart.

If crystallographic directions other than those marked in the standards are desired, they can be easily located on the stereographic projection from the positions of the cube poles. Therefore, there is no need to index many of the Laue spots. As a matter of fact, it is our opinion that a minimum of indexing of the standards is an aid to more rapid analysis.

It should be pointed out here that there are a number of errors in the standards of Majima and Togino. The errors of indexing can be easily corrected, however, with the aid of equations for crystallographic relations or with standard projections of the poles of planes. Another point con-

FIG 10—Laue patterns of the face-centered cubic lattice for determining $\alpha-\beta'$ in a preliminary analysis.

cerns the voltage used on the X ray tube. Referring to standard 45-0 of the body-centered cubic lattice as published by Majima and Togino,⁴⁶ it is observed that {321} Laue spots are present. A voltage of 35 kv was used according to their report; but 40-45 kv peak voltage is needed theoretically to bring out these particular Laue spots. On the other hand, the same Laue spots are absent in our 45-1 standards exposed at 40 kv peak voltage and show only on patterns taken at higher voltages.

Analysis

PRELIMINARY ANALYSIS

A preliminary analysis involves determining which standard Lauegram of the 75 mounted between glass plates resembles most closely the unknown pattern. To obtain agreement some

films obviously have to be turned over. They also have to be held in the correct rotational position. When held properly, the [111] zone always falls between 6:00 and 7:30 o'clock except near 45-35.3 where Laue spots of the zone fail to register on the photographic film. The [001] zone lies between 1:30 and 3:00 o'clock except near 0-0 where it fails to register on the film. The [101] zone lies between 9:00 and 12:00 o'clock and fails to show near 45-0.

The [111] and [001] zones for the body-centered cubic lattice often can be correctly recognized at a glance; determining the standard to use for analysis is then an easy matter. When difficulty arises in finding the proper standard, film nets can be used as illustrated in Fig 17 and 18 to help identify the zones. The zone of Laue spots falling on the meridian line of the Leonhardt net in Fig 17 clearly

shows a sequence of angular separations of 30° (spots on 20, 50, 80, 110 and 140 latitude lines) thus indicating that the zone is of the $\langle 111 \rangle$ form. This same relationship as well as a 135° relationship for a $\langle 100 \rangle$ zone is shown even more clearly in Fig 18, the common (110) Laue spot falling on the base line. Having established the [111] and [001] zones of this pattern, the identification of the Lauegram as one very near 29-15 follows quickly upon comparison with the standards.

The [101] and [001] zones of the face-centered cubic lattice generally need to be recognized for a rapid identification of the unknown pattern. When difficulty arises, the film nets again can be used as an aid. Although the isogonal net shown in Fig 5 is not constructed for direct application on a [101] zone, it can be used if a rough interpolation only is needed.

FINAL ANALYSIS

In order to plot the orientation of a crystal in stereographic projection, a method for measuring the angles δ and ϕ (see Fig 2 and 3) is required. The δ , ϕ analyzer shown in Fig 19 with δ ranging from zero to 30° and ϕ from zero to 360° fills this need very well; a complete analysis of a film often can be made with it in a time of five minutes or less. A film net as shown in Fig 6 but photographed on glass is mounted in a frame and located over a good source of light. To provide a carrier for the Lauegram, a circular clear piece of film approximately 8 in. in diam is clamped to a metal ring, which is graduated in degrees and is seated in the base concentrically with the film net in such a way that the assembly is free to rotate with the Lauegram while the clear film remains in contact with the surface of the stationary film net. The Lauegram is held against the surface of the clear film with scotch tape, the central spot of the Lauegram coinciding with the center of the film net and the pinprick falling on the single radial line (a reference line) when the scale reads 270. In this position the reference direction *R.D.* should coincide with the zero direction on the scale.

Continuing with the Lauegram used as an illustration in Fig 17 and 18, standard 29-15 from the index file is now laid over the Lauegram on the analyzer. An identified Laue spot is then brought to the reference line of the net. A final position with the (010)

FIG 20—Analyzer employing a Greninger net and showing correct setting for a zone of Laue spots.

Laue spot falling at angles 16° and 187° for δ and ϕ respectively is illustrated in Fig 19. The angles δ and ϕ are essentially polar coordinates and must be so used in plotting the pole of the (010) plane in stereographic projection as was explained in the discussion of Fig 3.* The (110) and another Laue spot (one with larger δ for greater accuracy) are similarly plotted to determine the [001] zone. With the [001] zone on a meridian line of a Wulff net, the pole of the (100) plane and the pole of the (001) plane—the latter coinciding with the [001] zone axis—can be located directly to complete the analysis for the orientation of the crystal involved.

If a zone axis is to be plotted directly, the angles for doing this are obtained upon placing the zone of Laue spots as parallel as possible to the meridian lines of the net and reading tilt and azimuth from the analyzer.

Final analyses by the present method actually are more difficult to make near some of the common symmetry positions than for other positions. For example, in the face-centered lattice the position 45-0 (twofold symmetrical) is more difficult to analyze than is 29-15 shown in Fig 14. Likewise 0-0 (fourfold symmetrical) for iron is one of the more difficult positions to analyze rapidly.

In the usual back-reflection Laue

method, however, symmetry conditions are a great aid to both preliminary and final analyses. Zones are generally more useful than individual Laue spots for plotting the orientation in stereographic projection. A suitable set of marked standards could be made for the more rapid identification of zones in back-reflection Lauegrams.

A convenient method for measuring tilt and azimuth on such patterns is shown in Fig 20. Here a Greninger net comprises part of the analyzer. The Laue pattern is 44-18 in α , β' coordinates. Angle coordinates for a $\langle 111 \rangle$ zone, which has been placed parallel to the meridian lines of the net, are a tilt out of the plane of the sample of almost 10° and an azimuthal angle of 191° . These angles can be used with a Wulff net to plot the zone axis in stereographic projection.

Latitude lines on the Greninger net are useful for determining directly angles between planes in the same manner described previously for the zero-tilt Leonhardt net. For example, a {112} Laue spot is 30° from the {110} spot, the strongest Laue reflection for the $\langle 111 \rangle$ zone shown in Fig 20.

Acknowledgment

The amount of work represented by the final marked standard Laue patterns is considerable. The production of the negatives and positives from

the original Lauegrams alone is quite a task and the authors are indebted to the Photographic Department of the General Electric Co. for completing this work. The authors are also indebted to Dr. Arthur A. Burr, of Rensselaer Polytechnic Institute, for helpful suggestions in the preparation of the manuscript and to Eugene F. Welter of the Metals Section for assistance in the X ray work.

The Vapor Pressures of Zinc and Cadmium over Some of Their Silver Alloys

C. E. BIRCHENALL,* Junior Member, and C. H. CHENG,* Student Member AIME

Introduction

The fundamental problem in the thermodynamics of solid solutions is the determination or calculation of the activities of the components as a function of temperature and composition. Since the theory of metals is not sufficiently developed to allow *a priori* calculation of these quantities, they must be obtained from experiment. C. Wagner¹ has reviewed the literature of this subject for the period before 1940. Although several important and extensive studies have been made in the meantime, the number of systems to which any sort of quantitative information can be assigned is vanishingly small. These data have become of great potential importance in studies of the structure of solid solutions² and intermetallic compounds, the nature of the diffusion process,^{3,4} and perhaps even the mechanism of mechanical deformation.⁵ For these reasons, it seems very worthwhile to extend the experimental data in this field.

Although there is little use in duplicating Wagner's review, attention should be directed to the most recently reported investigations. A brief enumeration of the methods of measurement previously employed also should be valuable. The most direct method is the determination of the partial pressure of the components in the vapor phase in equilibrium with the solution. Both equilibrium and kinetic methods have been tried in metal systems, but almost exclusively on liquid phases. Only in the case of carbon in iron alloys and in the copper-zinc system have extensive measure-

ments been made which include solid phases.

When one of the components is an element, such as nitrogen or carbon, which forms compounds which are very volatile and stable at normal temperatures and pressures (CH_4 , CO_2 , CO , NH_3), it is frequently possible to equilibrate mixtures containing these (such as $\text{CH}_4\text{-H}_2$, $\text{CO}_2\text{-CO}$, $\text{NH}_3\text{-H}_2$) independently with the elements (C, N) and with the metal (Fe, Ni, etc.). Such measurements have been made for carbon in iron, iron-silicon, and iron-manganese alloys by Smith⁶ and in iron and iron-nickel alloys by Toensing.⁷ Differences between carbon activity values at the same temperature and carbon content when carbon is introduced from $\text{CH}_4\text{-H}_2$ mixtures or CO-CO_2 mixtures indicate that the effects of hydrogen and oxygen in the system are not negligible, and one can only hope that the true value lies somewhere between these sets of results, probably nearer the $\text{CH}_4\text{-H}_2$ data since hydrogen is less soluble in iron than oxygen. This is essentially an equilibrium method, although flowing gas is employed.

A kinetic method has been employed which consists of sweeping an inert gas (generally hydrogen) over the alloy at

a series of rates, condensing the metal vapor out, and analyzing it. The metal content can be extrapolated to zero flow rate (equilibrium). Wejnarth's⁸ work on Cd-Mg and Zn-Mg is a good example of this frequently used method. A variant of this consists of equilibrating a known volume of inert gas with the alloy, sweeping it out quickly, and analyzing for metal. In common with the above method, it has the disadvantage that the "inert" gas is generally somewhat soluble in the alloy. Moreover, the former continuously displaces the system from equilibrium and may give low values if solid diffusion is involved.

The dew point method applied by Hargreaves⁹ to the alpha and beta brasses and by Schneider and Stoll¹⁰ to Al-Zn avoids the introduction of another component to the system, but is useful only in systems in which one component is much more volatile than the other. The alloy sealed in one end of an evacuated silica tube is heated to the desired temperature. The temperature of the other end is lowered until droplets of the volatile component condense. When the temperature is raised slightly, the droplets will evaporate. By careful adjustment of temperature, the range between evaporation and condensation can be narrowed appreciably. An independent determination of the vapor pressure of the pure volatile component is necessary to give the partial pressure over the alloy. This is the method employed here to determine the vapor pressures of zinc and cadmium over their silver alloys up to 34 pct in cadmium and 76 pct in zinc. The former involves only the α solid solution, but the latter covers the α , β , γ , and ϵ fields.

In recent determinations, Herbenar, Siebert, and Duffenback¹¹ used the

absorption of light to determine the concentration of zinc in the vapor phase over copper-zinc alloys. This is probably the method most free from objections arising from disturbance of equilibrium.

To calculate thermodynamic activities with pure metals as the standard states, independent determinations of the vapor pressures of pure components are necessary. For many metals, these have been made by two general types of measurement—the Knudsen method of effusion through an orifice and the method of free vaporization from a surface. The latter usually involves an assumption about the accommodation coefficient of the surface, and insofar as this is in doubt, the data obtained by the method are questionable. Therefore, the Knudsen method is more desirable. A recent experimental triumph is the determination of the vapor pressure of graphite in this manner.¹²

The calculation of thermodynamic activities from vapor pressure data has been described in a recent paper by Birchenall and Mehl³ for similar data on copper-zinc alloys. The methods are the same here. Another method sometimes employed in the determination of activities involves the measurement of the electromotive force of electrolytic cells. This is only feasible when the electrode reactions can be established beyond reasonable doubt and the cells are reversible in nature.¹³

Experimental

APPARATUS

With the exception of a few minor changes, the apparatus was similar to that of Hargreaves.⁹ The alundum furnace tube ($18 \times 1\frac{1}{4}$ in. id) was heated by three main resistance windings, with auxiliary coils to heat the tubes to the observation windows and the end plugs which were inserted to avoid draughts of cold air. The fine adjustment coil was movable in the direction along the tube. A low power cathetometer telescope was used to observe the droplets in the cooler end of the tube. A sketch of the apparatus appears in Fig 1.

TEMPERATURE CONTROL

Since the accuracy and reproducibility of this experiment are dependent chiefly upon the control and measurement of the temperatures at the ends of the fused quartz sample

tube, considerable attention has been devoted to these factors. The voltage across each resistance winding could be adjusted independently of the others with "Powerstats." For long heating periods, automatic control equipment was employed. Fluctuations in temperature were quite small after the furnace had been stabilized. It was possible to achieve a controlled temperature difference of 400°C between the ends, considerably more than required in these systems.

SAMPLE PREPARATION

Silver powder (99.9 pct, lot no. 4203-D, U. S. Metals Refining Co.) was melted by induction heating in a graphite crucible, the inner walls of which were coated with alundum cement. Metallic zinc (99.99 pct) or cadmium (99.95 pct) was added making allowance for vaporization losses. The melt was stirred gently with a fine quartz tube and allowed to stand for about 2 min. before being permitted to freeze in the crucible. After a thin layer of the surface was machined off, the ingot was sealed in an evacuated pyrex

capsule and homogenized for 24 hr at 650°C . From this a cylinder was machined about $\frac{5}{8}$ in. high by $\frac{7}{16}$ in. diam and a shallow well drilled in one end to receive the thermocouple protection tube. The samples weighed about 10 g.

PROCEDURE

The specimen was sealed in a transparent quartz tube after flushing several times with dry hydrogen and pumping to a few microns pressure. The tube was inserted in the furnace and heated overnight, the high end stabilized by a controller. The run began by lowering the temperature at the other end slowly until droplets condensed in the field of the telescope. These were reevaporated by raising the temperature. Then the cycle was repeated several times, more slowly, to narrow the range between condensation and evaporation. The differences could be reduced to about 2°C at 10 mm pressure, 3°C at 5 mm pressure, and $4\text{--}5^{\circ}\text{C}$ at 1 mm pressure. The times required to establish these were about 15 min. at 10 mm and 2 hr at 1

mm. The true equilibrium temperature was assumed to lie midway between the condensation and evaporation temperatures.

It was customary to begin with a specimen temperature about midway between the extremes then take the upper and lower points. This prevents overlooking changes which might occur progressively in the alloy to produce errors which would appear systematic if the temperature was always changed in the same direction.

SAMPLING

Samples for chemical analysis were taken from chips removed in shaping the samples before the run, others were machined off after the run. In only one case did these disagree by more than duplicate analyses on the final sample. This indicates that the homogeneity of the cylinders was quite satisfactory. Even if heterogeneity existed on a scale too small to be detected by the sampling method, it would have little effect on the results if the surface was representative. Vapor transport would quickly homogenize the surface where the determination was really made.

In a number of alpha Ag-Zn runs, the droplets formed at the low temperature end were collected and analyzed to determine the validity of the assumption that the condensate consisted of nearly pure zinc. Only the lowest zinc sample showed even a trace

of silver, too small to be determined quantitatively. Under the conditions of the analysis, it could not have been as great as 0.1 pct. This was checked by spectrographic analysis which also revealed minute traces of iron, silicon, magnesium, and copper.

Because of its greater volatility, conditions were even more favorable in the cadmium case, and no attempt was made to analyze the droplets.

ERRORS

Although no exact determination of the errors is possible, a reasonable estimate may be given. These are principally of two types—those associated with establishment, measurement, and control of temperatures and those relating to the composition of the sample and droplets. Errors may also be introduced into the calculations due to errors in the vapor pressure data for pure zinc and cadmium, but it is believed that the equations K. K. Kelley¹⁴ employed here are correct to within a few per cent.

Temperatures were measured with chromel-alumel thermocouples standardized against the freezing point of pure aluminum and a Bureau of Standards secondary standard couple. At these low operating temperatures, no contamination or recrystallization of the couples was observed. There was a possibility of error in the failure of the couples to measure the effective temperature of the sample or droplets

due to the steep thermal gradient in the furnace. However, care was always taken to see that the specimen covered one thermocouple well, and the droplets formed on the other. A 1°C error in temperature reading produced a relative error of about 1½ pct in the calculations. It seems probable that the error from this source averages less than 5 pct for individual points and less when several points are correlated as below.

Of the compositional errors, those arising from impurities appear to be negligible. Pure metals were used in melting, and any oxygen introduced would be tied up as ZnO. The latter would make the analyzed Zn content slightly higher than that participating in the process. To minimize this, the surface was cleaned several times before sealing in the quartz tube. The spectrographic analyses indicate that the zinc may have reduced a trace of silicon from the quartz tube.

Heterogeneity of composition may have been present from three sources. Since the specimens were made from castings, some segregation may persist even after fairly long annealing. But the experiment itself is an annealing process, and the samples taken at the end should represent the real composition well. Furthermore, the reproducibility of points was found to be quite good at different stages during the run.

Long heating in a temperature gradient could produce a concentration gradient in the specimen, but the vapor pressure would still approach the true value for the average composition and temperature. It is unlikely that this effect is important here.

Repeated evaporation and condensation might cause considerable differences between the surface and the interior of the sample. In the 20 cm long tube of about 1.3 cm id, it is possible to have 0.01 g of zinc in the vapor phase at 100 mm pressure. This is increased by the necessity of forming droplets of finite size for visual resolution.

There should also be a time dependent hysteresis in the surface layer, as zinc is first evaporated, then condensed. However, by slowing the rate of temperature changes, the gap could be narrowed to the point that the equilibrium value was in little doubt.

Since the analytical deviations average between 1 and 2 pct, the calculated activities may contain errors which aggregate to more than 10 pct for

FIG 2—Graph of 1/T₁ vs. 1/T₂ for alpha silver-cadmium alloys. T₁ is the temperature of the alloy in equilibrium with cadmium droplets at temperature T₂.

FIG 3—Phase diagram of the silver-zinc system according to Andrews, Davies, Hume-Rothery and Oswin, with the activities of zinc referred to pure liquid zinc as the standard state. The circled points are those of Schneider and Schmid.

single points, but the data taken as a whole should be better than this.

Discussion of Results

The Clapeyron-Clausius equation

$$\frac{\partial \ln p}{\partial T} = \frac{\Delta H}{RT^2} \quad [1]$$

relates the vapor pressure, p , the absolute temperature, T , the gas constant, R , and the heat of vaporization, ΔH . Over a narrow range of temperature, ΔH will be nearly constant. Then

$$\ln p = -\frac{\Delta H}{RT} + C. \quad [2]$$

If p_1 is the partial pressure of zinc or cadmium over the alloy at temperature T_1 , and p_0 is the vapor pressure of zinc or cadmium over the pure liquid metals at T_2 , they will obey

$$\ln p_1 = -\frac{\Delta H_1}{RT} + C_1 \quad [3]$$

$$\ln p_0 = -\frac{\Delta H_0}{RT} + C_0 \quad [4]$$

At equilibrium, $p_1 = p_0$, and

$$\frac{\Delta H_1}{R} \left(\frac{1}{T_1} \right) = \frac{\Delta H_0}{R} \left(\frac{1}{T_2} \right) + C_1 - C_0. \quad [5]$$

Since R , C_1 , C_0 are constants and ΔH_1 and ΔH_0 are nearly so, this is nearly a linear equation in $1/T_1$ and $1/T_2$. This is the form in which the experimental data were plotted for correlation. The

best smooth curve was drawn through the points, and values were read off at intervals of about 20°C. (As an example, the curves for silver-cadmium are given in Fig 2.) Tables 1 and 2 list the vapor pressures, activities, and activity coefficients for zinc and cadmium calculated from points read from these curves. It is possible by standard methods to calculate the other thermodynamic quantities for these systems as exemplified by the free energy of solution which will be discussed below.

Liquid zinc and cadmium have been chosen as the standard states for the calculation of activities using the vapor pressure equations of K. K. Kelley.¹⁴ Other standard states might have been employed. Particularly in the alpha solid solution ranges, the infinitely dilute solutions offer an attractive state independent of other determinations, but this is hardly suitable for extension to the other phases. Of course it is a simple matter to recalculate these points on the basis of any arbitrary reference state.

Since the activity coefficients for the constituents of two phase alloys depend on the location of the phase boundaries, it was necessary to assume that the diagram for silver-zinc given by Andrews, Davies, Hume-Rothery, and Oswin¹⁵ is correct. This diagram is

given in Fig 3 with the activities of zinc marked on it. Any deviations in this diagram will produce errors in the computed values given here. This problem did not arise in silver-cadmium because no two phase alloys were studied.

The few activities reported for solid phases in both systems by Schneider and Schmid¹⁶ are considerably lower than those observed here. This may be a result of allowing too little time for solid diffusion to supply zinc to the vapor. This seems especially likely since their liquid values seem to be quite consistent with the results obtained by extrapolating our data to the solidus line and with our one liquid point on silver-zinc.

It is interesting to examine the alpha solid solutions of the systems Cu-Cd, Ag-Cd, Ag-Zn, and Cu-Zn from the point of view of size factor, electronegativity, and the free energy of solution of liquid zinc or cadmium in silver or copper. According to Weibke and Matthes,¹⁷ the heat of formation is least in the case of Cu-Cd and increases in the order given to Cu-Zn. This is also the order for the free energy decrease given by Biltz.¹⁸ The data of Schneider and Schmid¹⁶ also leave little doubt that in the liquid phase Cu-Cd shows the least decrease

in free energy and Cu-Zn the greatest, but Ag-Zn and Ag-Cd are too close to separate. Using the Gibbs-Duhem equation (see ref. 3), it is possible to obtain activities for silver at 25 at. pct zinc or cadmium for 700°C. The partial molar free energy, $\Delta\bar{F}$, of a substance relative to some arbitrary standard state is given by

$$\Delta\bar{F}_i = RT \ln a_i, \quad [6]$$

and the total free energy change for a binary solution (a measure of its stability) is obtained from this by

$$\Delta F = X_1\Delta\bar{F}_1 + X_2\Delta\bar{F}_2, \quad [7]$$

where the X 's are mole fractions.

Substituting from above this becomes

$$\Delta F = RT(X_1 \ln a_1 + X_2 \ln a_2). \quad [8]$$

This is the equation employed in calculating ΔF in Table 3, corresponding to the reaction

Ag or Cu (solid) + Zn or Cd (liquid) \rightarrow solid solution (25% Zn or Cd)*

From this table, it appears that the stabilities of the Ag-Zn and Ag-Cd solutions are nearly identical with Ag-Cd slightly favored.

The size factors for the four systems are as follows: Cu-Zn, 1.04; Ag-Cd, 1.03; Ag-Zn, 1.08; Cu-Cd, 1.16. Only Cu-Cd exceeds the 1.15 set as the limiting value for extensive solubility. This is confirmed by the observation that Cu-Cd has an alpha solid solution extending to less than 2 at. pct cadmium while the other systems extend to 30 to 40 pct. Thus the repulsion due to large discrepancies in size makes very little free energy available through mixing copper and cadmium. Schneider and Schmid¹⁶ found that liquid solutions of copper and cadmium show positive deviations from ideal behavior while all the other systems above give negative deviations.

The most reasonable measure of electronegativity should be the Fermi energy of the crystalline metals. The differences should give a rough measure of the attraction between the components. Using the values of Slater,¹⁹ the following are obtained (in volts): Cu-Zn, 1.1; Ag-Cd, 0.8; Ag-Zn, 0.4; Cu-Cd, 2.3. Cu-Cd has already been eliminated by the size factor, so the solutions are favored in the decreasing order Cu-Zn, Ag-Cd, Ag-Zn as observed.

* The liquid states of Zn and Cd are used as reference states since they are the stable phases of the pure metals at the temperatures considered. Later in the discussion of short range order one of the assumptions requires the use of a fictitious solid reference state.

| α | 620 | 1.30 | 16.0 | 0.0813 | 0.274 |
| α | 600 | 0.90 | 11.2 | 0.0804 | 0.271 |

It is apparent that the size factor and electronegativity correlate quite well in a qualitative way with the observed free energies for these metallic solid solutions. However, it should be emphasized that it is unlikely that constants for the pure metals in themselves give an adequate representation of the state of these atoms in solution. This need not detract from their great usefulness which has been demonstrated in many instances.

The similarity in the deviations from ideal solution laws in the systems Ag-Zn and Ag-Cd to those in Cu-Zn suggests that the same considerations regarding the progression of structures applied earlier to the brasses² should also apply here. The progression of structures α , β , γ is, of course, very similar with only moderate shifts of phase boundaries corresponding to the quantitative differences in activities. The great differences in the free energies in the Cu-Cd system are reflected in the very different appearance of its phase diagram.

Short Range Ordering

Our attention has recently been called to an error in ref. 2* where Eq (18) relating the equilibrium constant, K , for the reaction of bonds

to the fraction, x , of bonds which are $B-B$ at 25 at. pct B has been mistakenly rewritten in Eq (19).

$$K = \frac{(1-4x)^2}{2x(1+2x)} = 4e^{-\Delta F^\circ/RT} \quad (\text{correct}) \quad (18)$$

$$K = \frac{(1-4x)^2}{2x(1-x)} = 4e^{-\Delta F^\circ/RT} \quad (\text{incorrect}) \quad (19)$$

ΔF° is the standard free energy for reaction (15).

When the values of x for 25 at. pct zinc in copper are recalculated for 950°C and 700°C, the first approxi-

* The authors wish to thank Professor C. S. Samis of the Univ. of British Columbia for discovering this error. The equation numbers from the earlier paper will be used in this section in parentheses.

mations give $\frac{1}{20.4} = (0.0490)$ and

$\frac{1}{23.0} = (0.0435)$ respectively. These

results are in good agreement with those of Guttman²⁰ calculated from the equation of Takagi,²¹

$$\frac{v_{AA} + v_{BB} - 2v_{AB}}{kT} = \ln \frac{(c-x)^2}{x(1-2c+x)} \quad [9]$$

x has the same meaning as above, c is the atomic fraction of component B in the solution, and $\Delta F^\circ = N(2v_{AB} - v_{AA} - v_{BB})$ where N is Avogadro's number. Eq 9 may then be rewritten in exponential form

$$e^{-\Delta F^\circ/RT} = \frac{(c-x)^2}{x(1-2c+x)} \quad [9a]$$

Inserting $c = \frac{1}{4}$, this reduces immediately to Eq (18).

Repeating the procedure used in ref. 2 for $c = \frac{1}{3}$ and $c = \frac{1}{2}$ and substituting these values in Eq 9a, again gave two sets of identical equations.

For

$$c = \frac{1}{3}, e^{-\Delta F^\circ/RT} = \frac{(1-3x)^2}{3x(1+3x)}$$

$$c = \frac{1}{2}, e^{-\Delta F^\circ/RT} = \frac{(1-2x)^2}{4x^2}$$

It therefore appears that the methods of Birchenall and Takagi are equivalent for the treatment of short range order.

For calculations of short range order, the pure solid materials make the most convenient reference states. For zinc and cadmium, this involves an extrapolation of the vapor pressure equations for the solid beyond the melting point. In the case of zinc, the extrapolation is probably fairly good but cadmium is rather uncertain. Nevertheless this has been done here in determining the activity coefficients referred to the solid, approximate bond energies, free energies for reaction (15), and the short range order for the systems Cu-Zn, Ag-Zn, and Ag-Cd for 700°C and 25 at. pct Zn or Cd. In an ideal solution x , the fraction of Zn-Zn or Cd-Cd bonds would be 0.0625 ($\frac{1}{16}$),

P = pressure of zinc or cadmium in mm. Hg over alloy.

P° = pressure of zinc or cadmium over pure liquid metal at the same temperature.

$a = P/P^\circ$, the activity of zinc or cadmium.

$\gamma = a/N$, the activity coefficient.

N = mole fraction of zinc or cadmium.

but in all three cases it is less than this. The tabulation follows (Table 4).

Using Darken's²² correlation of the activity coefficients for solid silver-gold solutions and Eq 9, the x 's have been calculated for mol fractions 0.25, 0.50, and 0.75 at 700°C and several temperatures along the solidus line. Even in this completely isomorphous system and so near the melting points the ordering is seen to be appreciable.

The scatter of data did not permit estimating the dependence of ΔF° on temperature for reaction (15) for silver and gold. Consequently, the mol fractions and x 's apply to either component, the deviations showing up most markedly in the value of x for the dilute component (Table 5).

Summary

The vapor pressures of cadmium in equilibrium with three alloys in the alpha solid solution field in silver have been measured over a temperature range of about 200°C. Similar measure-

ments have been made on nine alloys of silver and zinc from 8 to 76 at. pct zinc and over a somewhat narrower temperature range. These alloys include the α, β, γ, and ε fields, as well as yielding activities along several of the liquidus lines.

The thermodynamic activities and activity coefficients have been calculated for the volatile component in each case. In the silver-zinc system, the activity coefficients of two phase alloys are based on the phase diagram of Andrews, Davies, Hume-Rothery, and Oswin.

At 700°C and 25 at. pct, the free energies of solution for liquid zinc and cadmium in solid silver have been computed for comparison with those of copper-zinc. The free energies of these systems have been compared with each other and copper-cadmium with respect to size factor, electronegativities and the progression of stable phases in the phase diagram.

The methods for calculating short range order developed by Birchenall and Takagi have been shown to lead to identical results. Application has been made to the alpha solid solutions of silver-zinc, copper-zinc, and silver-cadmium at 700°C and 25 at. pct zinc or cadmium and to the silver-gold

system. These calculations indicate a greater proportion of A-B bonds than would be present in ideal solution.

Acknowledgments

This work was done on a contract between the Office of Naval Research and the Metals Research Laboratory of Carnegie Institute of Technology. The chemical analyses were performed by Martha M. Helzel. Many of the runs were carried out by Wilbert Walker, and a few of the alloys were melted by William J. Reichenacker. Their assistance is gratefully acknowledged.

Sintering Characteristics of Minus Sixty-five and Twenty Mesh Magnetite

ALAN STANLEY,* Junior Member AIME, and JOSEPH C. MEAD

Introduction

The MacIntyre Development of the National Lead Co. is located at Tahawus, N. Y. The operations involve the mining and concentrating of a titaniferous iron ore to produce an ilmenite concentrate and a magnetite concentrate.

Construction of the MacIntyre plant was commenced during the summer of 1941, when world conditions threatened to cut off the supply of Indian ilmenite. An open pit mining operation was developed and the crushing and milling equipment put in operation in July 1942. A general description of the operation was given in the Adirondack Issue of *Mining and Metallurgy* for November 1943. The metallurgy of the mill operation was described by Mr. Frank R. Milliken,* Plant Manager, National Lead Company, MacIntyre Development, and presented at the AIME New York Meeting, February 1948.

The magnetite concentrate produced in the milling operation was too fine (minus 20 mesh) to be used directly in iron blast furnace operation, and most of the magnetite had to be stockpiled in 1942 and 1943.

In 1943, the Defense Plant Corp. built a Greenawalt sintering plant at Tahawus, N. Y., to put the magnetite concentrate in a more suitable form for use in the iron blast furnace.

The Greenawalt sintering plant consists of three 10 by 25 ft sintering pans

designed to produce 1800 gross tons of sinter per 24 hr. The vacuum to each pan is produced by two Greenawalt fans in series, pulling approximately 30,000 cu ft of air per minute at 50 in. water gauge vacuum. The plant started operation in August 1944. The present plant production averages 25 tons per operating pan hour (approximately 224 lb per operating hour per square foot of grate area) of plus 1 in. sinter.

Raw feed to the plant consists of 61 pct magnetite, 4 pct anthracite coal culm, and 35 pct minus 1 in. return fines which are conveyed to a pug mill where the materials are mixed thoroughly and water added to give the mixture 5.5 to 6 pct moisture. The mixed prepared feed is conveyed to two 4 by 10 ft vibrating screens where the minus 1 in. plus $\frac{5}{8}$ in. return fines are screened out and discharged into a surge bin for use as a hearth layer. The minus $\frac{5}{8}$ in. prepared feed is discharged into another surge bin for use as prepared feed.

A charge car, electrically operated, having a capacity of one charge of prepared feed and several charges of hearth layer, lays a thin layer of plus $\frac{5}{8}$ in. return fines and $9\frac{1}{2}$ in. depth of

prepared feed into the pans. A fluffing roll and a vibrator on the car fluffs and spreads the prepared feed into the pans.

An ignition car, electrically operated, ignites the top of the bed with a 30 sec flash burn. The $9\frac{1}{2}$ in. bed sinters in approximately 13 min. Dumping the pan, and recharging and igniting the bed requires 2 min.

To improve the quality of the ilmenite concentrate produced in the mill and to reduce the amount of titanium dioxide lost in the mill tailings and in the magnetite product, extensive research work and pilot plant operations have been done on grinding the crude ore to minus 65 mesh size (rather than to minus 20 mesh) and concentrating it by a combination of magnetic separation (for magnetite recovery) and flotation (for ilmenite recovery). These tests have proved successful in increasing ilmenite recovery and grade.

With the development of the ilmenite flotation process to a stage where a full scale flotation plant was in the design stage, the problem arose of handling the 65 mesh magnetite concentrate that would be produced. In order to study and solve the problems of handling and sintering the 65 mesh magnetite in the sinter plant, a pilot sinter plant was secured from John E. Greenawalt.

The effect of using 65 mesh magnetite in the sintering operations was then studied on the 2.4 sq ft test pan, operating under conditions as similar to the large plant as could be set up in the laboratory.

A series of tests were run in the test pan on present sinter plant feed that had been mixed in the plant pug mill. An average production and an average quality of sinter produced in this series

San Francisco Meeting, February 1949.

FIG 1—Sinter pan and kerosene burner.

FIG 2—Instrument panel.

of tests was established as a "Standard" (8.8 lb per min) to compare the sintering of minus 20 mesh magnetite with that of minus 65 mesh magnetite.

The high points on each series of tests were repeated twice as a check on the original, to be sure that some unknown variable did not cause the change in the sintering performance. A test run of 10 pans was made on the mixture found to give the best production and quality.

Procedure

The pilot sinter plant included a sintering pan 20¾ by 16¾ in. and 9 in. deep, an ignition hood, a pressure kerosene burner for ignition, a dust collector, and a 400 cfm vacuum fan rated at 54 in. of water (see Fig 1 and 2 for instrument panel, sinter pan and kerosene burner).

Vacuum was recorded on a Bristol meter, and exhaust temperatures were read from an electrical pyrometer.

Magnetite of 65 mesh was prepared by grinding stockpile (20 mesh) magnetite, to the desired size, in a batch ball mill, and filtering in a laboratory pressure filter, Table 1.

The moisture obtained by this method of filtering was too high for pilot plant use (averaging about 9 pct) and it was necessary to dry a portion of the magnetite prior to its use in the sintering operation.

For the final "production run" tests, rod mill screen undersize (20 mesh) was ground to 65 mesh, and the magnetite was concentrated in a laboratory

Crockett.

Coal was obtained from the sinter plant stockpile, and when necessary, ground in a ball mill to the desired size. After several tests had to be discarded because of poor results caused by coal with high ash content, all coal samples were submitted to the laboratory for ash determination. In order to eliminate one variable, only coal with a 10 pct or less ash content was used in the test work.

Sawdust, when needed, was obtained from local mills; limestone and slaked lime were obtained from the Chazy Lime and Stone Co.

The return fines, unless otherwise noted, were obtained by crushing plus 1 in. sinter, produced in the pilot plant, in a jaw crusher and rolls and screening it to the desired size on a laboratory vibrating screen.

Screens for screening the sinter were made locally, as were sample racks and storage bins for the raw materials. A ¼ yard gasoline concrete mixer was connected to an electric drive and used for the mixing of all batches. Balances and a hot plate were provided for moisture determinations, and an electric clock with a sweep second hand was used for timing the tests.

A group of five persons was found to be the most efficient, as continuous test work required constant work by one man grinding magnetite and coal, one man preparing sized return fines, two men preparing batches for burning, and one man completing the necessary calculations and paper work. The last three men were required when the batches were burned.

Each batch mixed contained enough material for two tests. The charge was calculated in advance. A weighted mixture of dry and filtered magnetite was added to the mixer. This material was then mixed for 5 min and a moisture determination made. Using this moisture it was possible to calculate the exact amount of magnetite that had to be removed or added to the mixer to leave the required weight of magnetite at 5 pct moisture.

Then the remaining materials were added dry, and the necessary amount of water to provide the required moisture was sprinkled, with a sprinkling can, into the revolving mixer. When trouble with pellet formation occurred, the procedure was changed so that the necessary water was added to the return fines, and then the wet returns were added to the mixer. The latter method was more satisfactory.

Each batch, unless otherwise noted, was mixed for 5 min again.

A 15 lb bedding charge (minus 1 in. plus ½ in. sinter) was added to the pan for each burn. This gave a bedding depth of 1 in. Then the sinter pan was filled, with a weighed amount of mix, and dumped by hand through a 1 in. screen. The bed then was made level by scraping off the excess material. The weight of the mix in the pan was obtained by difference. The ignition hood was lowered into place over the pan, and the pressure kerosene burner was ignited, as the vacuum was turned on, and ignition took place for 30 sec. The hood was then raised. A record was made of the exhaust temperature as the burning proceeded and vacuum was recorded continuously with the Bristol meter. When the bedding on the grate bars glowed red (viewed by means of a mirror mounted to make the grates visible through a hole covered with glass in the bottom of the pan) the vacuum was turned off and the

Table 1 . . . Screen Analysis of Magnetite Products

| | +28 | +35 | +48 | +65 | +100 | +150 | +200 | −200 |
|--------------|-----|------|------|------|------|------|------|------|
| 20 mesh..... | 8.3 | 16.4 | 19.5 | 14.8 | 12.1 | 9.2 | 5.2 | 14.5 |
| 65 mesh..... | | | | 3.0 | 11.2 | 19.8 | 15.8 | 50.2 |

Note: All references to 65 and 20 mesh magnetite refer to minus 65 and minus 20 mesh material.

sintered charge was dumped by inverting the pan.

The results of the first pan of the mix were usually poor because a cold pan did not approximate actual operating conditions. The second, or hot pan, gave results that could be compared more directly with sinter plant practice.

After each pan was burned, the material was passed over a 1 in. Ty-Rock screen three times. The material remaining as plus 1 in. was "sinter." The minus 1 in. material was passed over a ½ in. Ty-Rock screen twice, and the plus ½ in. material was "bedding." The remainder of the material (minus ½ in.) was "return fines" (note: in all references to return fines in this paper, the bedding is excluded).

In order to have a strength comparison of the sinter formed by various mixes, a "quality" figure was initiated. This figure was determined by screening the cold (the plus 1 in. sinter was allowed to air cool overnight) sinter in the same manner as above. The weights of the plus 1 in. and the plus ½ in. were combined, and this total weight was divided by the weight of the hot 1 in. sinter to obtain relative "quality."

Cycle time was figured by adding 2½ min to the burning time to allow for dumping and recharging the pan. Theoretical production in pounds per minute was determined by dividing the pounds of plus 1 in. sinter by the cycle time. In quite a few tests the amount of bedding and return fines produced was not sufficient for repeat operations. Because of this some of the plus 1 in. sinter had to be taken to provide the amounts of these materials needed. Actual production was then the weight of plus 1 in. sinter remaining after bedding and return fines requirements were met, divided by cycle time.

Discussion of Factors Investigated

The following factors were investigated during the test period:

(1) return fines, (2) coal, (3) moisture, (4) slaked lime and miscellaneous reagents, (5) oxidation, (6) limestone, (7) sawdust, (8) pellets, (9) "dust," (10) mixing time, and (11) production runs.

RETURN FINES

As far as is known, there is no sinter plant in the United States that employs sized return fines as a necessary

FIG 3—Results of return fines series.

metallurgical requirement for its operation. Mr. Worm Lund, on a visit to MacIntyre from Sweden, suggested the possibility of sized return fines in the sintering of 65 mesh magnetite.

In the test plant at 20 mesh, return fines were not necessary for the production of good sinter. In many cases the return fines were detrimental to test plant production. This is especially true when the returns consisted mainly of raw magnetite, coal, and dust from the dust collectors.

For sintering 65 mesh and finer magnetite, return fines are absolutely necessary for sinter production. If efficient operation and economical sinter are to be had, it is necessary to have these return fines fall within definite size ranges. The secret of sintering fine concentrates is to obtain proper porosity in the "bed" so that air can be uniformly distributed throughout and burning can progress.

A series of tests were run using minus ½ in. plus 3; minus 3 plus 6, minus 6 plus 10, minus 10 plus 20, minus 10 plus 35, and minus 20 plus 35 mesh return fines. The best results were obtained from the minus 10 plus 35 mesh tests. Because of the difficulty that would be incurred by screening to these close sizes, a series was run using minus ½ in. plus 0, minus 3 plus 0, minus 6 plus 0, and minus 10 plus 0. The results of this series can be seen in Fig 3. These tests were run with 4.0 pct coal and 25 pct return fines.

As can be seen (Fig 3) the best re-

sults were obtained using minus 10 mesh plus 0 return fines. The best percentage of this size return fines was determined by a series of tests (Fig 4). The results were satisfactory only as long as the minus 35 mesh portion did not exceed 25 pct of the total return fines weight. (This then would give a calculated minus 10 plus 35 mesh return fines figure of 18.75 pct of the total weight of the charge.)

A study of the results obtained using various amounts and sizes of return fines indicated:

1. Proper porosity is essential in producing sinter economically:

- Too much porosity causes too rapid burning and results in poor sinter.
- Insufficient porosity increases the burning time beyond economic limits.

2. Excess returns weaken the sinter and cause a drop in production.

3. By proper control of the size and amount of returns it should be possible to sinter magnetite finer than 65 mesh.

4. More efficient sinter plant operation could be obtained if the dust from the dust collectors and the finer portion of the returns were returned to the original source of sinter plant feed (for example: to magnetite filter).

A 20 mesh magnetite will sinter without the addition of return fines, providing adequate bedding is supplied, but blast furnace operations object to fines; this requires that the fine material be screened out and recirculated.

FIG 4—Results of various percentages of minus 10 plus 35 mesh returns.

FIG 5—Effect of various percentages of anthracite culm 4 and 5 buckwheat coal on sinter production using 65 mesh magnetite.

COAL

Coal is used in MacIntyre sintering as the most economical local source of carbon.

The amount and size of coal used is an important factor in a sintering operation.

As can be seen in Fig 5, 4.0 pct coal produced the best results in sintering 65 mesh magnetite. Both greater and lesser amounts of coal tended to slow the burning time and reduce the production of sinter. Insufficient coal did not produce enough heat for proper sintering and excess coal caused too high a temperature, resulting in slagging and overoxidation with resultant poor sinter. This overoxidation was caused by an oxidizing atmosphere, and while reduction may have taken place during the initial phases of the burning, the final result was excess oxidation.

On the theory that coal used in sintering should be approximately the same particle size as the magnetite, the coal for the sintering tests was ground to 65 mesh. This fine coal, at first, seemed to help sinter production, but sawdust was being used in conjunction with it. As testing progressed,

FIG 6—Effect of various mesh sizes of coal on sinter production using 65 mesh magnetite.

satisfactory results were not obtained, and it was decided to test various sizes of coal. These tests (Fig 6) proved that fine coal, rather than help, did much to deter good sinter production. The No. 4 and 5 buckwheat anthracite culm, as received for 20 mesh sintering, gave excellent results and made it possible to eliminate sawdust from the mix.

The fine coal tended to plug most voids, and made proper air flow impossible. The coarser coal left large voids as it burned, causing lower vacuum and faster burning time.

MOISTURE

The amount of water that can be added to a 65 mesh magnetite "mix" is limited. The "mix" will sinter, if all other proportions are correct, at a moisture between 6 and 8 pct, with the best results obtained at 7.5 pct moisture (Fig 7).

FIG 7—Effect of various percentages of moisture on sinter production with 65 mesh magnetite.

If the moisture is too high, the mix becomes semifluid and it is impossible to draw air through the bed. Thus, ignition is impossible. If the moisture is low, holes tend to form as the material is pulled through the grates. The air, following the path of least resistance, is drawn through the holes and thereby short-circuits the bed. Poor burning results and less sinter is produced.

With 20 mesh magnetite, a wider moisture range is possible. Good sinter was produced with a moisture as low as 3 pct, and as high as 8 pct. However, with 20 mesh magnetite, the percentage of moisture required is closely related to the amount of dust present in the returns. If there were more than 35 pct of minus 35 mesh material in the return fines, it was necessary to use a moisture of 7.5 pct (production with the same mix at 7.5 pct moisture was 10.8 lb per min and at 6.0 pct moisture, production was 9.6 lb per min). If the returns contain less than 35 pct minus 35 mesh material, best results are obtained with a 6 pct moisture.

SLAKED LIME AND MISCELLANEOUS REAGENTS

In an effort to reduce burning time, and thus increase production, slaked lime was added to the charge. A 10 pct increase in production was obtained with the addition of 0.7 pct lime to the 65 mesh mix (Fig 8).

If an excess of lime is added, the charge will burn hot and fast, with little sinter being produced. It is thought that the lime causes an increase in the surface tension of the water. With this higher surface tension, the water would fill less voids in the

Table 2 . . . Effect of Lime on Varying Amounts of Coal

| | Production (Lb per Min) | Cycle Time (Min) | Temperature Exhaust Gas Degree C | Quality | Vacuum In. of Water | | Per Cent Lime |
|--------------------|-------------------------------|------------------------|--|---------|---------------------|-----|------------------|
| | | | | | Start | End | |
| With 3 pct coal... | 5.5 | 9.0 | 520 | 81.5 | 61 | 48 | 0.75 |

Table 3 . . . Effects of Various Reagents on 65 Mesh Magnetite Sinter

| Reagent | Per Cent Reagent | Production, Lb per Min | Per Cent Plus 1 In. Sinter | Quality | Cycle Time, (Min) |
|-----------------------|---------------------|---------------------------|-------------------------------|---------|----------------------|
| Standard..... | | 9.0 | 65.1 | 78.9 | 13.1 |
| Lime..... | 0.7 | 9.9 | 63.6 | 78.0 | 11.5 |
| Detergent..... | 0.005 | 8.1 | 64.2 | 86.0 | 15.0 |
| Oleic acid..... | 0.05 | (would not burn) | | | |
| Calcium chloride..... | 2.0 | 9.7 | 61.4 | 74.8 | 12.0 |
| Pine oil..... | 0.05 | 5.1 | 52.2 | 88.2 | 20.5 |
| Zinc stearate..... | 0.5 | (would not burn) | | | |
| Aluminum dust..... | 0.5 | 5.8 | 54.8 | 78.9 | 18.0 |

mix, thus leaving greater and more numerous voids than possible with un-adjusted water. With more numerous voids, a greater volume of air was drawn through the bed, lowering the vacuum, decreasing the burning time, and causing a higher burning temperature. The addition of excess lime increased the surface tension to such an extent that an excess volume of air was drawn through the charge, causing such rapid and hot burning that little sinter was produced.

If the percentage of lime was held constant and the coal percentage dropped, less sinter was formed because of higher burning temperatures. Higher burning temperatures slag the sinter.

The results of Table 2 show that with 3 pct coal and 0.75 pct slaked lime, the mix burned hotter, and gave poorer results than those obtained using 4 pct coal and 0.75 pct slaked lime. This can be explained by the knowledge that a higher percentage of carbon causes excess slagging. This slagging reduces the amount of voids, and this tends to slow the burning rate. This shows, again, how critical the addition of lime would be in actual plant practice. If lime were added in excess, production would drop. If the amount of lime remained constant and the percentage of carbon dropped, production would again drop. Thus, if lime is used in actual plant practice, efficient metallurgical and quantity controls must be provided.

In order to check the surface tension theory, a series of tests were made using the following reagents (Table 3): (1) detergent ("Dreft"), (2) oleic acid, (3) calcium chloride, (4) pine oil, (5) zinc stearate, and (6) aluminum dust.

It is known that a detergent reduces the surface tension of water. Thus, if a

detergent is added to the mix, a poorer sinter should result, because with a lower surface tension, the water would fill more voids. The results obtained by test work checked with this idea. When 50 g of detergent were added to the mix, the mix became "putty-like" in appearance and semifluid in nature. The sized return fines were completely disintegrated when they were placed in water containing a detergent. When this mix was added to the pan it was impossible to draw air through it, and thus it could not be ignited.

Calcium chloride, which gives a substantial increase in the surface tension of water, was next added to the mix. The calcium chloride decreased the burning time, but produced a weak sinter. The sinter cake actually expanded during burning when calcium chloride was in the mix. Why this expansion took place is unknown. Calcium chloride could not be used in sinter plant operation because of the large amounts of chlorine gas liberated during the burning; however, it was used in the pilot plant because it was known to increase the surface tension of water.

All other reagents tried gave poor results.

OXIDATION

For a short while during the test work, it was thought that the oxidation of the FeO to Fe₂O₃ was an important factor in strong sinter. To check this point many assays were made on magnetite feed, and sinter produced from this magnetite. As a result of a study of these assays it is thought that oxidation to a certain extent does produce stronger sinter by causing the iron molecules to share oxy-

FIG 8—Effect of various percentages of slaked lime on sinter production with 65 mesh magnetite.

gen atoms. When oxidation progresses too far, the iron is oxidized completely and no longer shares oxygen atoms, thus producing weaker sinter. When oxidation is low, there is little sharing of oxygen atoms and again the sinter is weak.

Table 4 . . . Effects of Oxidation upon Quality of Sinter

| Magnetite | | | Sinter | | | Qual- ity |
|-----------|-------|--------------------------------|--------|-------|--------------------------------|--------------|
| Fe | FeO | Fe ₂ O ₃ | Fe | FeO | Fe ₂ O ₃ | |
| 57.0 | 31.04 | 46.99 | 56.8 | 21.78 | 57.06 | 75.8 |
| 56.7 | 31.61 | 45.91 | 56.0 | 16.52 | 61.68 | 87.8 |
| 58.0 | 32.33 | 46.97 | 56.5 | 9.63 | 70.05 | 72.8 |

Table 4 is representative of the average assays completed, and shows weaker sinter on both the high and low oxidation samples.

LIMESTONE

Because of the cheaper costs of limestone compared to slaked lime, it was thought desirable to check the effects of limestone in the "mix." The limestone was sized from minus 6 plus 10, minus 10 plus 20, minus 20 plus 35, and minus 35 plus 65 mesh. In no case did the limestone help. This was probably caused by the fact that the heat necessary to slake the lime evaporated all the moisture before the limestone was slaked, and thus the effect of the slaked lime on the water was lost.

SAWDUST

Sawdust was helpful when 65 mesh coal was used in the mix. The sawdust

FIG 9—Effect of various percentages of sawdust on sinter production with 65 mesh magnetite.

had a tendency to “fluff” the mix in the pan, and it also made voids for air passage as the mix was burned. Fig 9 shows a high point for sawdust addition. As the percentage of sawdust was increased above 5, the mix burned very hot and fast and sinter production dropped. Sawdust elimination simplified the general problem because of the difficulties that its handling would have entailed if it were needed for 65 mesh magnetite sintering. The use of No. 4 and 5 buckwheat coal eliminated the need for sawdust.

PELLETS

A rotary mixer was used for pilot plant mixing. During the mixing of some batches, pellets were formed by magnetite building up around particles of return fines. The coarser the return fines, the larger the pellets would become. These pellets interfered with sinter production by causing short-circuiting of air around them because they had no porosity. Therefore they were unable to be sintered. The pellets were baked by the heat around them, but crumbled when subjected to the slightest pressure. No figures were obtained and the only method of making these determinations was by visible observation.

In sinter plant operation, pug mills are used for mixing and this problem should not occur. However, if pellets do form, some method to eliminate them must be provided. This does not infer sintering of a completely pelletized charge was undertaken. In all cases the pellets were mixed with unpelletized material, and under such conditions, were detrimental.

DUST

Dust is defined in this test work as material in the return fines, less than 65 mesh for 20 mesh magnetite sinter and minus 200 mesh for 65 mesh magnetite sinter. After it was known that excess fine material would reduce sinter production with 65 mesh material, tests were made to determine what effects “dust” would have on minus 20 mesh material. It was found that if the moisture was increased as the percentage of “dust” increased, the amount of “dust” in the “mix” had little effect on sintering of 20 mesh magnetite.

MIXING

Early in the project, several mixing tests were run using pug mill discharge. When this material was further mixed in the rotary mixer, a sharp production increase was noted. This mixing was checked again at the end of the project, and no increase in production could be attained by further mixing. In some cases production fell off after additional mixing, probably caused by water filling the voids in the return fines. It is thought that the pug mill blades, and other plant conditions were responsible for the poor results obtained during the first testing, but with the pug mills in good shape, as far as blade wear is concerned, a complete mix should be attainable. It was found that a 5 min rotary mix, after the magnetite had been brought to the correct moisture, gave the best results for rotary mixing in the test plant.

PRODUCTION RUNS

When the test work was completed it was necessary to test the best results. For this purpose, several pans were burned in rapid succession to see how the “mix” would react in a hot pan over a period of time. The recommendations made were on the basis of the production run results.

Conclusions

The best quality and quantity of sinter on this test pan were obtained with the following mix:

- 4.0 pct coal
- 25.0 pct return fines¹(minus 10 mesh plus 0)
(at least 18.75 pct minus 10 mesh plus 35 mesh)
- 70.3 pct magnetite (minus 65 mesh size)

0.7 pct slaked lime.

The average production on the test pan with the above “mix” was 9.9 lb per min or 246 lb per hr per sq ft of grate area. This is slightly higher than average production in the sintering plant pans on minus 20 mesh magnetite.

The pilot plant work indicates that minus 65 magnetite can be sintered in the sinter plant if close control can be maintained over the following items:

1. Adequate amount of bedding material (minus 1 in. plus ½ in. return fines for hearth layer.
2. Sized return fines (minus 10 mesh plus 0).
3. Anthracite coal (size and moisture percentage).
4. Moisture percentage in the “mix.”
5. Magnetite (moisture percentage).
6. Percentage of magnetite, coal, lime, and return fines in the prepared feed to the plant.

The results obtained in the sinter testing show that a more accurate metallurgical control on overall operation will be necessary for sintering minus 65 mesh magnetite than is needed in present plant operation for sintering minus 20 mesh magnetite.

Before the present sintering plant can handle minus 65 mesh magnetite, the plant flowsheet will have to be changed to include the conveying, cooling, screening, storing, and weighing of both return fines and bedding material.

Because of the difference between the size of the test pan (2.4 sq ft grate area) further development work will be needed in the sintering plant. A production run of at least two months would be required on minus 65 mesh magnetite to study the effect of the finer mesh size magnetite on the operation and maintenance of the plant.

Equilibrium in the Reaction of Hydrogen with Oxygen in Liquid Iron

MINU N. DASTUR,* Student Associate, and JOHN CHIPMAN,† Member AIME

The importance of dissolved oxygen as a principal reagent in the refining of liquid steel and the necessity for its removal in the finishing of many grades have stimulated numerous studies of its chemical behavior in the steel bath. From the thermodynamic viewpoint the essential data are those which determine the free energy of oxygen in solution as a function of temperature and composition of the molten metal. A number of experimental studies have been reported in recent years from which the free energy of oxygen in iron-oxygen melts can be obtained with a fair degree of accuracy for temperatures not too far from the melting point. Certain discrepancies remain, however, which imply considerable uncertainty at higher temperatures; also several sources of error were recognized in the earlier studies. It has been the object of the experimental work reported in this paper to reexamine these sources of uncertainty and to redetermine the equilibrium condition in the reaction of hydrogen with oxygen dissolved in liquid iron.

The reaction and its equilibrium constant are:

Here the underlined symbol $\underline{\text{O}}$ designates oxygen dissolved in liquid iron. The activity of this dissolved oxygen is known to be directly proportional to its concentration^{1,2} and is taken as equal to its weight percent.

The closely related reaction of dissolved oxygen with carbon monoxide has also been investigated:^{3,4,5}

The two reactions are related through the water-gas equilibrium:

$$K_2 = \frac{p_{\text{CO}} \times p_{\text{H}_2\text{O}}}{p_{\text{H}_2} \times p_{\text{CO}_2}} \quad [3]$$

and with the aid of the accurately known equilibrium constant of this reaction, it has been shown⁵ that the experimental data on reactions [1] and [2] are in fairly good, though not exact, agreement.

Experimental Method

Great care was taken to avoid the principal sources of error of previous studies, namely, gaseous thermal diffusion and temperature measurement. The apparatus was designed to provide controlled preheating of the inlet gases and to permit the addition of an inert gas (argon) in controlled amounts, two measures found to be essential for elimination of thermal diffusion. A known mixture of water vapor and hydrogen was obtained by saturating purified hydrogen with water vapor at controlled temperature. This mixture, with the addition of purified argon, was passed over the surface of a small melt (approximately 70 g) of electrolytic iron in a closed induction furnace. After sufficient time at constant temperature for attainment of equilibrium the melt was cooled and analyzed for oxygen.

GAS SYSTEM

A schematic diagram of the apparatus is shown in Fig 1. Commercial hydrogen is led through the safety trap *T* and the flowmeter *F*. The catalytic chamber *C*, held at 450°C, was used to convert any oxygen into water-vapor. A by-pass *B* with stopcocks was provided so that the hydrogen could be introduced directly from the tank to the furnace when desired. From the catalytic chamber the gas passed through a water bath *W*, kept at the desired temperature by an auxiliary heating unit, so that the gas was burdened with approximately the proper amount of water vapor before it was introduced into the saturator *S*.

All connections beyond the catalytic chamber were of all-glass construction. Those connections beyond the water bath were heated to above 80°C to prevent the condensation of water vapor. After the saturator, purified argon was led into the steam-hydrogen line at *J*, and finally the ternary mixture was introduced into the furnace.

THE SATURATOR

The saturator unit comprised three glass chambers, as shown in Fig 1, the first two chambers packed with glass beads and partially filled with water, and the third empty. Each tower had a glass tube with a stopper attached for the purpose of adjusting the amount of water in it. The unit was immersed in a large oil bath, which was automatically controlled with the help of a thermostat relay to constant temperature, $\pm 0.05^\circ\text{C}$, using thermometers which had been calibrated against a standard platinum resistance thermometer. The performance of the saturator over the range of experimental conditions was checked by weighing the water absorbed from a measured volume of hydrogen; the observed ratio was always within 0.5 pct of theoretical.

FIG 1—Diagram of apparatus.

FIG 2—Furnace arrangement.

FURNACE ARRANGEMENT

The furnace arrangement is shown in Fig 2. A glazed-surface silica tube *N*, 24 in. long and 2 in. id, was used throughout. It worked satisfactorily and was impermeable to gases at elevated temperatures. The furnace was equipped with water-cooled brass top *K* and bottom *S* and rubber gaskets *L*. The brass head *K* was fitted with a sight glass *J* made of pyrex glass, 1/2 in. diam and 1/16 in. thick. A gas inlet and outlet were provided at the top and

bottom of the furnace respectively. A small silica tube, 1/2 in. od and 5 in. long, was used to carry the mixture into the furnace. It was fixed to the furnace head by means of an asbestos gasket *F*. The preheater tube *C* was suspended from the small silica tube.

The alumina crucible *A* was placed inside an outer alumnum thimble *P*, resting on an alumnum disc *U* which was in turn supported on top of an alumnum tube *Q*, 1/2 in. id, and steel tube *R* which passed through the bottom by means of a rubber gasket and which

could be slid up or down as desired. This proved to be very effective in positioning the melt inside the induction coil *B* to get the desired electrical coupling. The power needed for melting was from 10 to 14 kw, supplied by a 35 kva high frequency unit, and only 5 to 8 kw were necessary to hold the metal at any temperature between 1535° and 1800°C.

THE PREHEATER

The preheater tube *C* made of alumnum, 1/2 in. id, was tapped with 12 threads to the inch for a length of 6 in.; a coil of platinum wire *D*, 0.025 in. diam, which served as the heating element, was screwed into position in the threads. Later on, a bigger and better preheater was made 9 in. long and with a heavier wire, 0.030 in. diam, using platinum-10 pct rhodium instead of pure platinum. This enabled the entering gaseous mixture to be heated up to the temperature of the melt before coming in contact with it. The leads were taken out through holes drilled in the preheater tube and were fastened to terminal connectors at *G*. The preheater was covered with an alumnum insulating sleeve *M*, 12 in. long and 1 1/2 in. diam, resting on an alumnum disc *U* and another sleeve *O*, 1 1/2 in. long and 1 3/4 in. diam, to prevent excessive radiation. The incoming gases came in direct contact with the heated platinum wire and hence the preheating was very efficient.

OXYGEN ANALYSIS

Oxygen analyses were made by the vacuum fusion method on an apparatus which has been used in this laboratory for over ten years. It had been calibrated previously against measured gas volumes and checked by exchange of samples with the National Bureau of Standards. Results reported are the mean of two or more concordant determinations.

AVOIDANCE OF THERMAL DIFFUSION

In a mixture of gases of unlike molecular weight any temperature gradient tends to produce corresponding composition gradient, the lighter gas diffusing toward the hotter region. This is a well known effect which has given rise to troublesome errors in many studies of gas-metal reactions. When the metal is heated by induction a sharp temperature gradient may be set up near its surface; in some of the early

FIG 3—Experimental values of the apparent equilibrium constant at 1563° C. Log K approaches a limiting true value with addition of inert gas of high molecular weight.

FIG 4—Calibration curve for optical pyrometer sighted on a clean surface of liquid iron.

studies of reaction [1] this resulted in apparent values of K_1 which are now known to have been too high.

A study of the factors affecting thermal diffusion⁶ indicated two practical methods of minimizing errors from this source. The first is the obvious one of preheating the gases entering the system so as to eliminate as far as possible the thermal gradient near the surface of the melt. The second is based upon Gillespie's⁷ simplified treatment of the phenomenon which showed that the thermal separation is diminished by admixture of a gas of high molecular weight. According to this theory the error in log K_1 should be proportional to the reciprocal of the mean square root of the molecular weight of the gas. Fig 3 shows the results of a detailed experimental study⁸ at 1563°C using three degrees of preheat, the apparent value of log K being plotted against the reciprocal of the mean square root of the molecular weight. From the data it was concluded that the error is eliminated by adequate preheating and greatly minimized by addition of a heavy gas. The average value using the highest, and apparently adequate, preheat agreed with results obtained at lower preheat by extrapolation to infinite molecular weight. In later experiments, including all those made above 1563°C, the preheater was operated at the same apparent temperature as the melt, corresponding to the highest preheat of Fig 3, and argon was added in the approximate ratio 4:1.

TEMPERATURE MEASUREMENTS

All temperature measurements were made by means of a disappearing-

filament-type optical pyrometer sighted on the clean surface of the melt. The following is a brief description of the calibration of this method, the details of which are published elsewhere.⁸ Two optical pyrometers were calibrated against a standard instrument using a tungsten strip filament lamp. A special beryllia crucible was constructed having a reentrant tube in the bottom which provided a small "black body" at the temperature of the molten metal contained in the crucible. This crucible filled with liquid iron was held in the furnace under exactly the same conditions as those used in equilibrium determinations. Simultaneous temperature readings were made on the metal surface and on the "black body" using duplicate windows and prisms and occasionally exchanging the positions of the two optical pyrometers.

Similar calibrations were carried out using a thermocouple instead of the lower optical pyrometer, the bead of the couple being inserted into the reentrant tube. For temperatures up to 1650°C a platinum-platinum-rhodium couple was employed; this was checked before and after use at the melting point of palladium. For higher temperatures extending to 1930°C an independently calibrated tungsten-molybdenum couple⁹ was used. The resulting calibration curve which was used throughout this study is shown in Fig 4. The estimated uncertainty in temperature measurement is less than $\pm 5^\circ\text{C}$ at the lowest and slightly greater at the highest temperatures.

Experimental Procedure

The charge consisted of about 70 g of

electrolytic iron which had been previously cleaned, pickled, washed and dried. This was held in a crucible of high-purity alumina. The whole system including the furnace was flushed out with hydrogen for about an hour. The saturator, the water bath and connecting tubing were brought to the desired temperatures.

Since the object of this series of experiments was to determine the effect of temperature upon the Fe-H₂O equilibrium, it was necessary to let the various melts attain equilibrium at different temperatures, the range covered being from 1563° to 1750°C. Frequent temperature measurements were made and in general these did not deviate more than $\pm 3^\circ\text{C}$ from the desired value. The optical pyrometer was occasionally checked against the melting point of iron. The flow rates were adjusted to give an argon-to-hydrogen ratio of approximately 4:1 in all heats.

Preliminary runs had demonstrated that under the experimental conditions equilibrium in the reaction of hydrogen with oxygen dissolved in liquid iron was attained within fifteen minutes. All heats were continued for a minimum of forty-five minutes under steady conditions after which the metal was cooled as rapidly as possible.

To increase the rate of solidification, attempts were made to quench the melt directly into water at the end of the heat. A deep tank was arranged so that the water level was above the bottom of the furnace tube, thus excluding air, and the entire furnace bottom with the crucible and its supports was dropped into the water. The resulting ingots were mostly irregular and unsound and of very high oxygen content. Substitu-

FIG 5—Effect of temperature upon the equilibrium constant

$$K_1 = \frac{p_{H_2O}}{p_{H_2} \times \% O}$$

tion of chlorinated biphenyl for water resulted in a high-carbon ingot. The method finally adopted was to lower the melt into the cold part of the furnace, simultaneously cutting off the preheater and increasing the rate of flow of argon. Solidification occurred in five to fifteen seconds.

Most of the ingots were sound with very little or no porosity. The ingots were cut into pie-sections with a hacksaw. Grinding and pickling were used to clean the samples which were analyzed for oxygen by the vacuum fusion method. This method gives the total oxygen content of the sample and includes all the oxygen which was in solution in the melt and any oxide particles which may be entrapped in the specimen. Microscopic examination showed that the ingots were fairly clean and contained no appreciable amount of foreign oxides.

Experimental Results

The series of experiments at 1563°C which have been discussed in connection with thermal diffusion lead to a value of K_1 at that temperature of 4.68 ± 0.15 . Results at higher temperatures are shown in Table I. It is to be noted that the oxygen content of all samples is far below the saturation value in the liquid and hence there was little chance for loss during cooling. There was no visible evidence of ejection of oxide and no marked segregation in the ingots examined microscopically. Oxygen analyses were usually duplicable within ± 2 pct; in the five cases of larger deviation it is uncertain whether the cause was analytical error or actual segregation.

The results are plotted in Fig 5 in which are also shown the average values at 1600° and 1700°C reported respectively by Fontana¹ and by Samarin.² The best line through the data is represented by the equation:

$$\log K_1 = 7050/T - 3.17$$

This agrees very closely with Fontana's average but deviates from that of Samarin by about 18 pct in the value of K at 1700°.

Thermodynamic Calculations

COMPARISON WITH DATA ON FE-C-O SYSTEM

From the equation given above for the temperature dependence of K_1 we obtain the following for the change in free energy:

The free energy change in the similar reaction of carbon monoxide with dissolved oxygen to form carbon dioxide is obtained from this with the aid of the free energies of the four gases involved. The data given in "Basic Open Hearth Steelmaking"¹⁰ are in excellent agreement with the most recent compilation of the National Bureau of Standards.¹¹ From them we find for the water-gas reaction:

When this is subtracted from Eq 1a the result is:

Several investigators have studied this

equilibrium but it is only the results at very low carbon content that can be directly compared with the equation. The data of Marshall and Chipman⁵ and of Vacher³ for carbon contents below 0.02 pct are shown in Fig 6. The straight line represents the equilibrium constant calculated from Eq 2a which is given by the expression:

$$K_2 = \frac{p_{CO_2}}{p_{CO} \times \% O}; \log K_2 = +8440/T - 4.53 \quad [2b]$$

It is noted that the calculated line falls within the limits of experimental uncertainty at all temperatures and in fact represents the experimental data very satisfactorily. The precision of the data for the Fe-C-O system is not as good as that for the steam-hydrogen equilibrium so that the agreement should be recorded only within limits of about ± 0.07 in $\log K_2$. This represents rather good agreement for high temperature data.

FREE ENERGY OF OXYGEN IN IRON

The free energy of formation of water vapor is given by the equation:¹⁰

When this is combined with Eq 1a we have:

FREE ENERGY OF LIQUID FERROUS OXIDE

The liquid oxide phase which exists in equilibrium with solid or liquid iron has a composition represented by the formula Fe_xO where the value of x is a function of temperature and, in the range considered here, lies between 0.96 and 0.99. The free energy of this equilibrium phase per gram atom of oxygen is obtained from its solubility in liquid iron and Eq 5. Its solubility^{12,13} is represented by the expression:

$$\log \% \text{O} = -6320/T + 2.734 \quad [6]$$

This may be paraphrased by the equation:

which, with Eq 5, gives:

This is equivalent to the partial molal free energy of formation of FeO in the liquid oxide of equilibrium composition. From this the oxygen pressure of oxygen-saturated liquid iron is:

$$\log p_{\text{O}_2} = -24,850/T + 5.22 \quad [7a]$$

COMPARISON WITH DATA OF DARKEN AND GURRY

The oxygen pressure of oxygen-saturated iron may be calculated also from the experimental data of Darken and Gurry.¹⁴ These investigators have found the ratio $p_{\text{CO}_2}/p_{\text{CO}}$ in equilibrium with iron and iron oxide over a wide range of temperatures, the pertinent values being reproduced in Table 2. From the known free energies of the several gases¹¹ we have:

$$K_8 = \frac{p_{\text{CO}_2}}{p_{\text{CO}} \times p_{\text{O}_2}^{1/2}}; \log K_8$$

$$= +14,550/T - 4.405 \quad [8a]$$

Values of K_8 are included in Table 2. From these data the logarithm of the oxygen pressure is found as given in the fifth column. The sixth shows the same quantity computed from Eq 7a.

Table 2 . . . Computation of the Oxygen Pressure of Oxygen-Saturated Iron

| Temp. °C | $\frac{p_{\text{CO}_2}}{p_{\text{CO}}}$ | $\log \frac{p_{\text{CO}_2}}{p_{\text{CO}}}$ | $\log K_8$ | $\log p_{\text{O}_2}$ (D and G) | $\log p_{\text{O}_2}$ (Eq 7a) |
|-------------|---|--|------------|------------------------------------|----------------------------------|
| 1371 | 0.282 | -0.550 | 4.447 | -9.99 | |
| 1524 | 0.208 | -0.682 | 3.690 | -8.74 | -8.61 |
| 1575 | 0.194 | -0.713 | 3.470 | -8.37 | -8.24 |
| 1600 | 0.187 | -0.728 | 3.363 | -8.18 | -8.05 |

The discrepancy between these two series of computed oxygen pressures is very small.* It is, however, a real discrepancy since the difference is greater than the apparent uncertainties in any of the subsidiary data. Perhaps the least certain of these is the solubility of oxygen in liquid iron. The data employed here are about 30 pct lower than those which were generally accepted prior to 1941.¹² However, if the older data are substituted the discrepancy becomes greater; thus the calculation upholds the lower solubility data.

It seems quite possible that in spite of all the careful calorimetric and spectroscopic work that has been done, minor errors may remain in the free energy values of the gases which would be large enough to account in part for the discrepancies found. Inconsistencies in values of the water-gas constant, K_8 , have been pointed out by Darken and Gurry¹⁴ and until these uncertainties have been removed the small discrepancy shown in Table 2 should be no cause for worry. We may conclude then that the present data are in good agreement with the requirements of the oxygen solubility of Taylor and Chipman and the equilibrium data of Darken and Gurry.

Summary

An experimental study has been made of equilibrium in the reaction of hydrogen with oxygen in liquid iron in the temperature range 1563°–1760°C. The primary purpose was to secure more dependable data by elimination of certain errors which were inherent in earlier work.

Errors of thermal diffusion in the gas mixture were eliminated by preheating the entering gas stream to the temperature of the metal. A further safeguard was the admixture of pure

*It is considered that earlier discrepancies below the melting point of iron have been adequately explained by Darken and Gurry.

argon with the gas stream in a ratio of about 4 to 1.

Temperature measurements were made by an optical pyrometer sighted on the clean surface of the melt. This system was calibrated in the range 1530°–1930°C against optical and thermoelectric measurements in a reentrant tube in the bottom of the crucible. This reduced uncertainties in temperature measurement to about $\pm 5^\circ$.

The experimental results are represented by:

$$K_1 = p_{\text{H}_2\text{O}}/p_{\text{H}_2} \times \% \text{O};$$

$$\log K_1 = 7050/T - 3.17$$

Related thermodynamic quantities are derived. The results confirm the oxygen solubility data of Fетters, Taylor and Chipman and are in good agreement with equilibrium data on the system iron-oxygen of Darken and Gurry.

Acknowledgments

The authors wish to express their thanks to Noble E. Hamilton and Nevzat A. Gökcen for assistance in building the apparatus and in conducting some of the experiments; also to Mrs. Catherine Kallal and Mrs. Marion Matheny for the vacuum fusion analyses. This research was begun with the aid of a grant from the Republic Steel Corporation and completed as part of Contract N5ori-07816, Task Order XVI, NR-031-186, Office of Naval Research.

[illegible]

Oxygen enriched air is being used paper, the use of oxygen enriched air Cottrell precipitator. The discharges

Most of the ore treated in the Trail metallurgical plants comes from Cominco's Sullivan Mine at Kimberley, B.C. At Kimberley the ore is milled to produce lead and zinc concentrates which are shipped to Trail for further treatment to metal.

A second section of the paper describes the use of oxygen enriched air in operations at the lead smelter. There oxygen enriched air is used in the blast to the lead blast furnaces and in the slag fuming furnace which recovers the lead and zinc contained in lead blast furnace slag.

The Use of Oxygen Enriched Air in the Suspension Zinc Roasters

Suspension roasting is carried out at Trail in converted standard 25 ft diam Wedge roasters. The 2nd, 3rd, 4th and 5th roasting hearths have been removed and the drying hearth covered over. Drying of the concentrate is done on the drying hearth and the 1st roasting hearth. The dried concentrate, after any lumps have been broken up in a ball mill, is fed to a single burner located in the upper part of the combustion chamber. Oxygen is introduced at the burner fan along with the gases from drying, returned combustion gases from the waste heat boiler outlet and the required amount of new air. Up to 60 pct of the concentrate settles out on the 6th roasting hearth, the rest passing out of the roaster. The product collected in the waste heat boiler is finished calcine, but the dust collected in the cyclones after the boilers is returned to the base of the combustion chamber where the sulphate is decomposed. Gases from the cyclones go to a

Following small scale tests started in 1933, oxygen enriched air has been used continuously in the suspension roasting of zinc concentrate in Trail, beginning in 1937. A significant factor in promoting its use in this operation was the availability of by-product oxygen from the Company's near-by Chemical and Fertilizer Division. To-day it is standard practice at Trail to use oxygen enriched air for zinc concentrate roasting.

High solubility of zinc requires that the sulphide sulphur and zinc ferrite in the calcine be kept low. These are both functions of temperature and time, with formation of zinc ferrite also dependent on contact between the iron and zinc particles. One of the inherent advantages of suspension roasting is that minimum time and contact are achieved. The limit on temperature is imposed by the fusion point of the concentrate and not by the need to control zinc ferrite formation. Operating temperatures are normally maintained within the limits of 1725° and 1850°F. A relatively low zinc sulphate in the calcine is required at Trail, and this results from discharging the calcine from the high sulphur dioxide atmosphere at a temperature above 1600°F.

* Manager, Metallurgical Division, Superintendent, Zinc Department, Superintendent, Lead Smelting Department, Superintendent of Development, Metallurgical Division, respectively. The Consolidated Mining and Smelting Company of Canada, Limited

The rate of elimination of sulphur from the concentrate and the control of zinc ferrite formation depend in practice principally on the following factors: 1. The composition of the concentrate. 2. The fineness of the concentrate. 3. The temperature in the roaster. 4. The time allowed for roasting. 5. The concentration of oxygen in the roaster.

The limitations that exist to restrict the operation are: 1. The size of the combustion chamber. 2. The capacity for grinding the concentrate. 3. The supply of oxygen.

To control sulphur dioxide concentration in the gas to the Acid Plant and maintain this at a maximum consistent with the production of satisfactory calcine is a secondary objective. For normal operation without the addition of oxygen the furnace outlet gas contains 8.5 pct SO₂, which corresponds to a concentration of 9 pct SO₂ in the combustion chamber. This latter concentration has a calculated theoretical maximum for Trail operations of about 14 pct, with no oxygen enrichment.

The controls used in roasting are: 1. Measurement of temperature in the combustion chamber. 2. Analysis of the calcine for sulphide sulphur. 3. Continuous recording of the sulphur dioxide concentration in the roaster gases.

The calculated and observed advantages of the use of oxygen enriched air in the suspension roasting of zinc concentrate may be summed up as follows: 1. Increased capacity and greater flexibility of operation. 2. Increased concentration of sulphur dioxide. 3. Greater overall heat recovery. 4. Faster starting up and steadier operations.

To calculate the oxygen enrichment of the new air used in suspension roasting is of little value where recirculation of gases to the burner is practised. Therefore, only the volumes of oxygen used are given. These volumes are at 0°C and 760mm Hg. The advantages will now be considered in detail:

INCREASED CAPACITY AND GREATER FLEXIBILITY OF OPERATION

Increasing the concentration of oxygen in the furnace gases has a marked effect on sulphur elimination in the suspension roasting of zinc concentrate. This most important advantage may be made use of in several ways. For a given roaster capacity where the sulphide sulphur in the calcine being produced is not the lowest that it is possible to attain, a calcine lower in sulphide

sulphur can be produced. If lower sulphide sulphur in the calcine is not required then the roaster capacity can be increased, or a coarser concentrate can be roasted. The foregoing indicates the greater flexibility of the roaster operation when oxygen is being used.

Current zinc concentrate treated at Trail is about 95 pct minus 200 mesh, and its analysis, and that of the corresponding calcine, are given in Table 1.

Table 1 . . . Typical Analyses of Normal Zinc Concentrate and Calcine

| | Zinc Concentrate, Pct | Zinc Calcine, Pct |
|-----------------------|-----------------------|-------------------|
| Zinc..... | 48.5 | 53.8 |
| Iron..... | 12.2 | 14.2 |
| Lead..... | 5.0 | 5.2 |
| Moisture..... | 4.5 | |
| Total sulphur..... | 32.3 | 1.5 |
| Sulphate sulphur..... | | 0.8 |
| Sulphide sulphur..... | | 0.7 |

The increased capacities obtained with increased additions of oxygen are shown in Table 2. Oxygen volumes are given in cubic feet per minute at N.T.P. and the supply analyzes 98.5 pct oxygen.

Table 2 . . . Increased Capacities Obtained with Increased Additions of Oxygen

| Rate of Roasting (tons per day) | Percent Sulphide Sulphur in Zinc Calcine with Increasing Oxygen | | | |
|---------------------------------|---|---------|---------|-----------|
| | 0 cfm | 200 cfm | 400 cfm | 1,000 cfm |
| 120 | 0.6 | 0.3 | 0.1 | |
| 140 | 1.3 | 0.7 | 0.4 | |
| 160 | 2.0 | 1.4 | 0.8 | 0.1 |
| 210 | | 3.7 | 2.1 | 0.3 |

From Table 2 it will be seen that an increase of 20 tons per day is realized for each 200 cfm of oxygen. At rates above 150 tons per day it becomes necessary to provide cooling in the combustion chamber to control the temperature there. This is normally accomplished by recirculating cooled gas from the waste heat boiler outlet back into the combustion chamber. At Trail the capacity limitations for recirculation required that additional cooling at very high tonnages be obtained by spraying water into the combustion chamber. This operation was found necessary during the test using 1,000 cfm of oxygen for the rate of 210 tons per day, about 20 lb of water per min. being sprayed into the lower half of the combustion chamber.

At increased roasting rates extra air

is also used with the increased oxygen. Indications are that the total oxygen supplied must be at least 50 pct in excess of the theoretical required. Although there is some increase in the excess oxygen required at the higher tonnages, this alone does not account for the increased rates of sulphur elimination. The full explanation must take into account the fact that the combustion chamber temperature tends generally to be higher at the higher rates.

INCREASED CONCENTRATION OF SULPHUR DIOXIDE

The first requisite of the roasting operation is to maintain a low sulphur in the zinc calcine. Gas strength at Trail is secondary to quality of calcine but is still important. Before installing the permanent oxygen supply for zinc roasting, it was decided to verify the effect of oxygen on gas strength. For this purpose a test was carried out at a normal roasting rate, using 140 cfm of oxygen. The increase in gas strength in the combustion chamber, as determined by the averages of a great many tests, was 0.3 units (9.0 pct SO₂ to 9.3 pct SO₂).

In appraising the long term benefit of oxygen as regards gas strength, many variables must necessarily be taken into account. Relatively large tonnages of acid are required at Trail, and, at times, this has necessitated the roasting of iron concentrate to supplement the gases from zinc roasting. Maximum theoretical gas strength is lower when roasting the pyrrhotite concentrate than when roasting the marmatitic concentrate. However, the use of oxygen in zinc concentrate roasting has assisted in maintaining high overall gas strength. At the same time it has also permitted higher tonnages of zinc concentrate to be roasted.

When allowances are made for all of the variables, there is always an increase in gas strength with increased oxygen, and at least as great as that obtained in the test reported above. Highest gas strengths are obtained when greatest quantities of oxygen are used to replace part of the air required for combustion.

The full range of gas composition in the combustion chamber has not yet been established by test work for comparison with theoretical requirements. In a high tonnage test the concentration of oxygen in the combustion chamber was 10.3 pct for a concentration of sulphur dioxide of 9.1 pct at the

FIG 1—Smelter oxygen system.
 Volumes shown are at 0°C and 760 mm Hg

 C—Check valve
 S—Spur gear valve
 V—Volume gauge
 P—Pressure gauge
 W—Water trap

furnace outlet. Of course this is not the maximum sulphur dioxide concentration reached in the combustion chamber, but it does indicate satisfactory conditions for high tonnages. Any extra oxygen in the roaster gases is an advantage in converting SO_2 to SO_3 in the Acid Plant.

GREATER OVERALL HEAT RECOVERY

The use of oxygen permits greater economy in heat recovery, both through increased capacity for drying the concentrates to be roasted and in increased steam production per pound of concentrate roasted. In a test to show the increased drying rate to be gained by using oxygen at a normal roasting rate it was established that 140 cfm of oxygen increased the drying capacity by about 40 pct. The results of tests carried out to determine the greater heat recovery from the gases are given in Table 3.

Table 3 . . . Results of Tests to Determine Heat Recovery from Gases

| Rate of Roasting (Tons per day) | Increase in Heat Recovery Using 400 cfm of Oxygen Pct |
|------------------------------------|---|
| 120 | 21 |
| 140 | 18 |
| 160 | 11 |

FASTER STARTING UP AND STEADIER OPERATION

Of less importance, but certainly a definite advantage of the use of oxygen in zinc roasting, is the greater speed that is achieved in getting the roaster up to temperature to produce satisfactory calcine. The lower temperature at which ignition of the concentrate occurs and the more rapid rise in temperature mean quicker starting after a shutdown. This results in a saving of fuel oil and minimum dilution of the roaster gases during starting up.

Fluctuations in the chemical and physical properties of the concentrates being fed, which occur particularly in treating a variety of customs concentrates, are more easily taken care of

when oxygen is being used to enrich the air for combustion. The normal procedure is to maintain the oxygen supply constant and make the other necessary adjustments. The result is a much steadier operation.

SUMMARY

Tests have been carried out using up to 1,000 cfm of oxygen on one suspension zinc roaster to obtain satisfactory operation up to 210 tons per day. The suspension zinc roasters at Trail are normally supplied with about 300 cfm of oxygen per roaster. The greatest single advantage has been to increase the individual roaster capacity from 120 tons per day to 150 tons per day. Gas strengths have been increased up to 5 pct. Heat recoveries have been increased up to 15 pct with the use of oxygen.

Advantages are achieved in proportion to the actual oxygen being used. Operation may be varied to obtain the maximum of the advantage desired at

a particular time. A much steadier roaster operation is achieved when oxygen is being used and the operation is more flexible.

Consideration is being given to the use of even greater quantities of oxygen. The object of this is to increase the capacity of present roasting equipment still further, and to obtain increased concentration of sulphur dioxide in the gases going to the Acid Plant for increased acid production.

The Use of Oxygen Enriched Air in the Slag Fuming Furnace and Lead Blast Furnaces

The use of oxygen enriched air has interested both ferrous and nonferrous pyrometallurgists for many years. The Trail Lead Smelter is fortunate in having available a limited supply of by-product oxygen from the Company's Chemical and Fertilizer Division. This fact led to the institution of a test program on the use of oxygen enriched air in both the lead blast furnaces and the slag fuming furnace.

To date most of the test work with oxygen enriched air at the Lead Smelter has been carried out on the slag fuming furnace, where both throughput and zinc recovery have been notably improved. The test work on the lead blast furnaces, although not very far advanced, has indicated a definite coke-saving and much smoother furnace operation.

The compressor delivering oxygen to the Lead Smelter handles a constant volume of 1,200 cfm, which is delivered to the Smelter at 15 psi. When less than 1,200 cfm of oxygen is used, air is introduced into the compressor to make up the difference and the Smelter receives a mixture of air and oxygen. This is fed into the bustle pipes on the slag fuming and blast furnaces with suitable measuring and control devices as shown in Fig 1. All volumes are given at 0°C and 760 mm Hg. 1,000 cfm of oxygen at N.T.P. equal approximately 65 tons per day.

SLAG FUMING FURNACE TESTS

Details of construction and operation of the slag fuming furnace have been published in *Transactions AIME 121*, "Slag Treatment for the Recovery of Lead and Zinc at Trail, B. C." by R. R. McNaughton. Briefly, the furnace is 10 ft wide by 24 ft long and 10 ft high with 36 2-in. tuyeres on each side. Pul-

verized coal and air are blown through the slag bath where the ZnO is reduced to Zn with the temperature of the bath maintained at about 2,200°F. Above the bath the Zn is oxidized again to ZnO. The furnace gases carrying the ZnO pass through a waste heat boiler where they are cooled to 900°F. They then pass through an economizer and finally reach the baghouses at something less than 220°F.

Normally the total volume of air to the furnace is approximately 16,000 cfm at 8 psi ga. Pulverized coal is used at a rate of approximately 200 lb per min. Operation of the fuming furnace is a batch operation and the furnace charge is 55 tons of molten lead blast furnace slag analyzing 16.5 pct zinc, 20 pct silica, 10 pct lime and 28 pct iron. Until recently the standard cycle of operations was 9 blows in 24 hr or 160 min. per blow.

The rate of elimination of the zinc from the molten slag charge depends in practice principally upon the following factors: 1. The composition of the slag. 2. The temperature of the slag. 3. The concentration of CO in the gases agitating the slag.

There are limitations in the existing plant equipment that control the operation, such as: 1. The gas handling capacity of the waste heat boiler and subsequent equipment. 2. The capacity of the blower to supply blast air. 3. The working capacity of the furnace (agitation of the charge must not splash slag into the flue). 4. The cooling capacity of the water jackets (limits furnace temperature).

Altogether about 100 tests, using up to a maximum of 26.5 pct oxygen in the blast, have been carried out on the slag fuming furnace to show the effect of oxygen. Some 30 of these were averaged to give the three sets of figures given in Table 5, which are graphed in Fig 2. In Table 6 the capacity and recovery increases for 23.4 pct oxygen in the blast (500 cfm oxygen added) are shown. In these calculations an empirical figure of 81 pct is used to obtain the tons of slag discharged from the furnace in relation to the tons of slag charged.

Although there is a slight increase in coal consumption the measurement of this has not been accurate enough for comparative purposes. The small increase in steam production is relatively insignificant.

Without the addition of oxygen the slag temperature, as measured by a locally developed continuous optical

temperature recorder, averaged about 2150°F. The use of oxygen has enabled temperatures slightly in excess of 2300° to be maintained. Limitations of the existing equipment prevent operation at higher temperatures.

The points of greatest interest on the curves in Fig 2 fall between blowing times of 100 and 140 min. In this range the rate of zinc elimination commences to fall off. It may be possible that the use of still greater proportions of oxygen to give slightly higher temperatures will permit the development of the operation of a continuous process. Of course, the economics of changing metal prices combined with production costs must be included in any calculations made to establish an operating program.

LEAD BLAST FURNACE TESTS

Details of operation of the lead blast furnaces at Trail have been published in *Transactions AIME Vol. 121*, "Lead Blast Furnace Practice at Trail, B. C." by G. E. Murray. The dimensions of the Trail furnaces have in some cases been altered. Therefore the significant dimensions are given in Table 4 and also the normal blast air volumes.

Table 4 . . . Furnace Dimensions

FIG 2—Effect of oxygen on slag fuming operation.

Interruptions in the supply of oxygen have made it impossible to carry through a prolonged continuous test on one blast furnace. Nevertheless the following figures will give some indication of advantages to be expected. A comparison of No. 10 blast furnace using 22.3 pct oxygen in the blast with No. 12 blast furnace using no oxygen showed a coke saving of 3.9 pct. Using 23.0 pct oxygen in the blast on No. 10 furnace and comparing the operation again with No. 12 blast furnace, the coke saving amounted to 12.1 pct. There were corresponding production increases of 20 pct and 30 pct for No. 10 furnace over No. 12. However, comparing the operation of No. 10 furnace using oxygen with its own previous operation for a comparable two months' period without oxygen, the increase in production amounted to only 15 pct for the total period it was using oxygen.

Oxygen has been valuable in blast furnace operation in preventing the formation of, or aiding to smelt out quickly, the crusts which generally form in the lower shaft or crucible. The normal time of smelting out these crusts is about 3 days, whereas the use of up to 27.5 pct oxygen in the blast enables them to be smelted out in one day or less by increasing bottom temperatures.

Although records do not indicate any marked increase in maximum furnace temperatures, slag temperatures are

on the average somewhat higher and better conditions do prevail in the upper shaft to give steadier furnace operation.

To summarize the rather small amount of test work carried out on the lead blast furnaces, it can only be said that indications point to a reduction in coke requirements of about 10 pct with an increase in furnace capacity of 15 to 20 pct for an oxygen enrichment giving 23.4 pct oxygen in the blast air. The regular use of 22.1 to 25.0 pct oxygen enriched blast with occasional applications up to 27.5 pct oxygen enrichment to smelt out crusts should prove to be economic in lead blast furnace operation. For enrichments greater than the above it will probably be necessary to make alterations in furnace design to achieve best results.

CONCLUSIONS

The value of oxygen in the slag fuming operation at Trail is in increased furnace throughput and higher zinc recovery. Further development work will require modifications in furnace design. These are already under consideration. Ultimately a continuous operation may be obtained.

In the lead blast furnaces the indications are that oxygen reduces coke consumption and increases furnace capacity. This work is continuing and will do so until the limits of the present equipment are reached. Alterations in

design will probably then be necessary as in the case of slag fuming.

The Precautions Necessary with the Use of Oxygen Enriched Air in Plant Operations

The use of oxygen enriched air in plant operations requires that certain precautionary measures be taken because of the following characteristics of oxygen:

1. Oil and grease may react violently with oxygen.
2. Spontaneous combustion occurs more readily in the presence of oxygen. The probability of a spark causing ignition during a static discharge is increased.
3. Oxygen accelerates combustion. It has been stated that the rate of acceleration increases rapidly up to a concentration of 40 pct oxygen with little difference noted between 40 and 100 pct oxygen.

The only positive method of preventing oxygen flow beyond a given point in a line is to insert a blind flange. It is strongly recommended that this procedure be adopted where any work is to be carried out in a system beyond a given cut-off point. Also, the system beyond this point should be completely purged of oxygen with large volumes of air.

A Thermodynamic Investigation of the System Silver-silver Sulphide

TERKEL ROSENQVIST*

Introduction

From the chemical, metallurgical, and mineralogical points of view, the importance of thermodynamic data for metal-sulphides and sulphur dissolved in molten metal has long been realized. Such data will give a basis for thermodynamic calculations of processes such as roasting and the distribution of sulphur between molten metal and slags. Furthermore, it will help us understand the chemical forces which tie sulphur to the metal and to the melt.

Thermodynamic studies of solid sulphides and the equilibria between solid sulphides and metals have been carried out in a rather large number of cases by several investigators. An excellent review of this work is given by Kelley.¹ On the other hand, very little is known about the thermodynamic properties of molten sulphides and of sulphur dissolved in molten metal. The only system which previously has been investigated in this respect is the iron/sulphur system.

The purpose of the present investigation was primarily to obtain further data for metal/sulphur melts and the system silver/sulphur was chosen, not because this system was expected to be of special interest in itself, but because the silver/sulphur system is a typical example of a metal/sulphur system. Because of the low melting temperatures, the work could be carried out without appreciable furnace and refractory difficulties. The sulphur in this system possesses a rather high escaping tendency compared to most other metal/sulphur systems. By the method employed (reaction with hydrogen to form hydrogen sulphide) this gives ratios P_{H_2S}/P_{H_2} up to 0.30, which may be determined accurately.

Thermodynamic investigations of the heterogeneous reaction $Ag_2S + H_2 \rightarrow 2Ag + H_2S$ have previously been carried out by Pelabon,² Keyes and Felsing,³ Jellinek and Zakowski,⁴ Watanabe,⁵ and Britzke and Kapustinsky.⁶

FIG 1—Apparatus for studies of gas-metal equilibria.

Their results are in rather poor agreement.

Experimental Part

PRINCIPLE

In the present investigation the escaping tendency of sulphur from the condensed phase was determined by the reaction:

The ratio P_{H_2S}/P_{H_2} is at constant temperature, directly proportional to the escaping tendency of sulphur and to its chemical activity in the condensed phase. (This ratio will subsequently be denoted by H_2S/H_2 .) From this ratio and its variation with temperature and with change in the com-

position of the condensed phase, thermodynamic quantities such as free energy and heat of reaction can be derived. The apparatus used is shown in Fig 1. The silver/sulphur alloy was placed in a crucible inside the refractory tube and mounted inside the furnace to the left. The tube was a part of a closed, gas-tight system in which the gas mixture could circulate until equilibrium was established. Circulation was maintained by the glass propeller to the right, driven by an external magnet, and promoted by the chimney action of the furnace. The gas passed up through the furnace, down into the crucible where it came in contact with the alloy, passed rapidly up through a narrow tube and out of the hot zone.

After equilibrium was established between the gas and the condensed phase, the composition of the gas mixture was determined from its density. In its circulation, the gas mixture passed through a chamber (lower right on Fig 1) containing a buoyancy-balance, where the density of the gas was determined by magnetic balancing. From the measured density,

corrected for pressure and temperature, the H_2S content, and consequently the $\text{H}_2\text{S}/\text{H}_2$ ratio were determined. For the gas compositions in question (1–25 pct H_2S) this method is more accurate than the usual chemical analytical methods for H_2S determination. The method further has the advantage compared with chemical analysis, that no gas is removed from the system during the determination. Thus, the progression of the gas-metal reaction could be followed by means of a large number of density determinations, until constant density indicated attainment of equilibrium. This would take from 4 to 5 hr, but the runs were always continued to a total of 12 hr. Prolonged heatings for another 24 hr, which were tried on some samples, produced no further change in the gas composition.

The equilibrium ratios could be determined for any number of temperatures during one heating, without need for withdrawal of gases for analysis or replenishment of the alloy.

After the end of each run, the sulphur content of the alloy was determined by analysis. In order to avoid any back reaction with the gas during cooling, the system was always evacuated to a few mm pressure after the last measurement had been taken (usually at about 1000°C) and cooled in vacuum.

For analysis, the alloy was oxidized by solution in hot concentrated nitric acid and the sulphate thus formed precipitated and weighed as BaSO_4 in the usual way.*

EXPERIMENTAL DETAILS

Materials

The silver/sulphur alloys used were made from electrolytically refined silver, 99.99 pct pure, and sublimed sulphur. Silver sulphide was prepared by heating together stoichiometric amounts of the elements in evacuated and sealed quartz tubes at a temperature of $500\text{--}700^\circ\text{C}$. This reaction was always complete. Silver/sulphur alloys of different compositions were obtained when weighed amounts of silver and silver sulphide were mixed and heated together during the run.

Thermocouple

For all temperature readings, a Pt-13 pct PtRh thermocouple was used. This thermocouple was calibrated by

*Thanks are due to the analytical laboratory of the Institute and particularly to Mr. R. E. Fryxell for the chemical analyses.

means of the melting points of antimony, silver, gold, and palladium—the last two by the wire-bridge method. (A short wire of the calibration metal is inserted in the thermocouple junction and heated until the wire melts, breaking the circuit.)

Furnace

A platinum resistance furnace was used. In order to obtain constant temperature for a period of time, the furnace was fed with current from a constant voltage transformer, and the input was regulated with a variable transformer. In this way, a temperature constancy of $\pm 2.5^\circ\text{C}$ was obtained for days. This is somewhat poorer than by a good temperature controller, but is more dependable in the long run. In the table of experimental results, the temperature is always given to the nearest 5°C .

Refractories

A tube of mullite was used for the main reaction tube. It proved to be absolutely vacuum tight during the entire work (which covered more than 30 runs over a period of about one year). The thermocouple tube and the outlet tube for the gas were of high grade porcelain, approximating mullite in their composition. However, leaks soon developed in the thermocouple tube. Therefore, an inner thermocouple tube of vitreous quartz, sealed gas tight to the porcelain tube, was used. After a couple of runs this quartz tube devitrified and had to be replaced.

A plug of alundum was cemented on to the thermocouple and outlet tubes and acted as a baffle to prevent heat radiation and gas convection to the upper part of the system.

The crucibles were of sintered high purity aluminum-oxide, (Pure-oxide from Norton Co.) free of silica. They stood up well and no chemical reaction seemed to have taken place between the crucible and the gas, or between the crucible and the alloy.

With exception of the crucibles, all other refractories contain some combined silica which gradually would be reduced by the gas at high temperatures. The refractories were therefore reduced with hydrogen at 1300°C before they were used. Nevertheless, some reduction always occurred during the runs. The water-vapor thus formed was absorbed in P_2O_5 placed in a small cup in the cold zone of the system.

Contamination of the alloy with

silicon from the refractories is a usual source of error in work of this kind; therefore a few of the alloys were examined spectroscopically for silicon. The alloys were found to be free of silicon.

The Buoyancy Balance

The buoyancy balance is in principle similar to what is earlier described by Stock,⁷ but certain changes have been made. It was built primarily of Pyrex glass. The beam was built of fine tubes of Pyrex glass with fine porcelain tubes fused on internally for increased rigidity. The bulb was blown of Pyrex glass to about 230 cm^3 and weighed less than 20 g. The counterweight was a Pyrex tube in which some lead was fused together with a small sheet of transformer iron. Eventually this tube was evacuated and closed so that the reaction gas did not come in direct contact with any metal parts. For the same purpose, the knife edge and the support for the balance were made of mullite porcelain, ground to shape and fused in place with uranium glass. The balance was operated by means of the external magnet M_1 (Fig 1) which contained a core of transformer iron. A current was passed through the magnet coil until a fine needle on the counterweight was just level with a corresponding stationary needle. In order to reduce the effect of magnetic hysteresis, the balanced position was always approached from a highly magnetized state, and in such a way that oscillation of the balance in the magnetic field was avoided. In this way, the effect of magnetic hysteresis was reduced to considerably less than 1 pct.

Between the readings, the balance was kept steadily in place by passing current through the lower magnet M_2 . This current, as well as the current for the propeller, was shut off the moment a density reading was taken.

The balance was so made that it was just balanced, without any magnetic influence, for a gas density slightly less than pure hydrogen at atmospheric pressure. This offers the widest operating range and greatest sensitivity for low H_2S contents.

The balance was calibrated by means of gases of known density. As such, dry air, nitrogen, helium and hydrogen were used. By varying the pressure of the calibration gas, a wide range of densities could be covered. The density of the gas was plotted as a function of the current in the magnet. The calibration was tested on known mixtures of

hydrogen and hydrogen sulphide and a satisfactory agreement with the calibration was found.

From the observed density of the gas mixture, the average molar weight M of the gas was derived. This gives the percentage of H_2S in the gas and the H_2S/H_2 ratio:

$$\%H_2S = \frac{M - 2.016}{32.06} 100$$

and

$$\frac{H_2S}{H_2} = \frac{M - 2.016}{34.08 - M}$$

The sensitivity of the balance in itself was about 0.3 mg corresponding to about 0.1 vol. pct of hydrogen sulphide. However, because the balance had a tendency to change position on its support, mainly due to vibration from the gas propeller, the calibration shifted somewhat back and forth. The balance was therefore recalibrated between every run. Nevertheless, the practical accuracy, as far as one could judge from parallel runs, would be about 0.2–0.3 pct H_2S which, for a gas of 20–30 pct H_2S , would represent a relative accuracy of 1 pct.

SOURCES OF ERROR

The value we are interested in is the ratio H_2S/H_2 of the gas when it is in equilibrium with the condensed phase in the hot zone. But the gas was analyzed at room temperature. Thus the question arises whether or not this analysis is representative of the hot gas.

Two different factors may tend to change the composition of the gas on cooling:

1. The gas mixture, in the hot zone, will hold a small amount of sulphur vapor as S_2 gas according to the equilibrium:

In the present work, the sulphur pressure in the hot zone, P_{S_2} , may be as high as 5 mm Hg.

The sulphur vapor will be carried along with the gas flow and on cooling, will react with H_2 to give H_2S . This will increase the ratio H_2S/H_2 in the cooled gas. That this reaction actually occurred is evident from the fact that no condensation of sulphur was observed in the cold part of the system.

In order to obtain the gas ratio H_2S/H_2 in the hot zone, the value observed in the cold zone must therefore be corrected. This correction has been disregarded by most investigators who previously have done work of this kind. But it can be shown that in extreme cases it may attain 10 pct.

FIG 2—Correction curves for H_2S/H_2 .

The curves to the left give the correction as a function of $H_2S/H_{2(obs)}$ for five different temperatures. The curves to the right give the correction as a function of temperature for three different values of $H_2S/H_{2(obs)}$.

If the correction should be done arithmetically on the basis of the observed gas ratio and the equilibrium constant for the reaction $2H_2S \rightarrow 2H_2 + S_2$, it would involve solving a third order equation. However, it can be done rather easily by a graphical method.

From a series of arbitrarily chosen values for the gas ratio in the hot zone, called $H_2S/H_{2(corr)}$, the equilibrium concentration of S_2 vapor was calculated. On cooling, each S_2 molecule combines with $2H_2$ molecules and gives $2H_2S$ molecules. Consequently, the expected gas ratio at room temperature, $H_2S/H_{2(obs)}$, could be calculated. The difference

$$\Delta H_2S/H_2 = H_2S/H_{2(obs)} - H_2S/H_{2(corr)}$$

was then plotted graphically against $H_2S/H_{2(obs)}$. When this was done for a series of temperatures, (for example, 1000, 1100, 1200, 1250 and 1300°C) a series of smooth curves were obtained (see Fig 2). From these curves, the correction for any experimental $H_2S/H_{2(obs)}$ could be made with sufficient accuracy. It will be seen that for temperatures below 1000°C and also for small H_2S/H_2 ratios, the correction is negligible.

2. The effect of thermal diffusion may cause considerable errors.

It was shown by Soret (1881) that a homogeneous aqueous solution, in response to a thermal gradient, develops differences in concentration in the cold and hot zones. It was later shown by Emmett and Schultz⁸ that the same effect occurred in mixtures of gases having different densities, and that this caused considerable errors in studies of gas-metal equilibria if performed in a *static* system. For the equilibrium of metal-metal oxides
